4. Frequent premature ventricular beats and asymptomatic nonsustained ventricular tachycardias are not associated with increased perioperative cardiac risk.

C. Permanent pacemakers and implantable cardioverter–defibrillators (ICDs). It is important to identify patients who have pacemakers or ICDs. Patients who are completely pacemaker-dependent should have their device checked within 3 to 6 months before surgery, and their device should be reprogrammed to an asynchronous mode during surgery (VOO or DOO); in certain models, a magnet can be placed over the device during surgery. Electrocautery should be used only briefly and with caution. Bipolar pacing minimizes the risk of electrocautery. After the operation, all pacemakers are interrogated to ensure that the settings are optimal and that no changes occurred during the operation or electrocautery. ICDs are programmed to off preoperatively and then reprogrammed to on after the procedure.

D. Hypertension. In general, patients with hypertension may be indirectly predisposed to perioperative myocardial ischemia, since CAD is more prevalent among these patients. In addition, because of the stiffness of the vascular system, they are predisposed to intraoperative hypotension; therefore, they should be **monitored closely during an operation**.

1. Patients with **mild or moderate** hypertension may undergo elective operations with continued medical therapy.
2. **Severe** hypertension (systolic blood pressure ≥ 180 mm Hg and diastolic pressure ≥ 110 mm Hg) should be controlled before the surgery. If possible, the operation is delayed until the pressure is consistently controlled. If urgent surgical intervention is needed, rapid-acting agents are used. β-Blockers are preferred, especially because they act as anti-ischemic agents as well.

3. Withdrawal of β-blockers and clonidine from patients undergoing long-term therapy with these agents **must be avoided** to prevent a rebound phenomenon.

E. Heart failure is associated with increased risk of perioperative morbidity. Identification of the etiology of heart failure is very important, since the treatment **depends on the cause** and overall clinical status.

1. Heart failure should be optimally controlled preoperatively with special attention to avoid over-diuresis, which can exacerbate postoperative hypotension.
2. Patients **with hypertrophic cardiomyopathy** need close monitoring of volume status, heart rate, and systemic vascular resistance to avoid intraoperative hypotension and hypovolemia that can lead to exacerbation of dynamic outflow obstruction.

IX. PERIOPERATIVE MEDICAL THERAPY

A. β-Blockers: Several trials and meta-analyses have examined the role of β-blockers in preventing perioperative cardiac complications. However, there remain multiple limitations in interpreting the data due to the paucity of randomized clinical trials, the lack of clear protocol for initiation and titration of β-blockers, and the lack of comparison between different agents. These limitations regarding the use of β-blockers perioperatively were acknowledged by the ACC/AHA in the latest ACC/AHA 2007 guidelines. Since the publication of these guidelines, POISE (PeriOperative ISchemic Evaluation) trial, a randomized, controlled trial of fixed higher dose, extended-release metoprolol started the day of surgery in more than 8,000 patients undergoing noncardiac surgery, prompted a 2009 ACCF/AHA focused update on the subject of perioperative β-blocker therapy. It demonstrated a reduction in primary cardiac events including cardiovascular death, MI, and cardiac arrest in those receiving perioperative β-blocker therapy. However, there was also an increased risk of stroke and total mortality in the β-blocker group suggesting that routine administration of high-dose β-blockers without dose titration may be harmful to β-blocker–naïve patients undergoing surgery. Specifically, β-blockade should continue during the intraoperative period and postoperative period to maintain a heart rate of 60 to 80 beats/min to avoid the pitfalls of this class of drug. In patients with indications for β-blockers, these agents can be continued indefinitely, and if there is no indication they should be continued for at least 7 days, and preferably 30 days after the noncardiac surgery.

1. β-Blockers should be continued in all patients undergoing surgery who are already receiving β-blockers for any class I guideline indication (to treat angina, arrhythmias, hypertension, etc.).
2. β-Blockers titrated to heart rate and blood pressure should be administered to all high-risk patients identified by myocardial ischemia on preoperative assessment undergoing vascular surgery.
3. β-Blockers titrated to heart rate and blood pressure are reasonable for patients undergoing vascular or intermediate-risk surgery in whom preoperative evaluation reveals CAD.
4. β-Blockers titrated to heart rate and blood pressure are reasonable for patients undergoing vascular or intermediate-risk surgery who have more than one clinical risk factor.
5. The usefulness of β-blockers is uncertain for patients undergoing vascular or intermediate-risk surgery who have only one or no clinical risk factor.
6. β-Blockers should not be administered in preoperative patients with absolute contraindications to the agents.

B. α_2-Agonists suppress the release of catecholamines and may decrease the incidence of cardiac events in patients with known CAD and at least one clinical risk factor who are undergoing noncardiac surgery.

C. The role of **calcium antagonists** is not well defined and requires further research.

D. **Statins.** There has been growing evidence suggesting an association between perioperative statin therapy and decreased perioperative cardiac complications. Definite indications for perioperative statin use await the results of ongoing and future clinical trials. However, it is important to note that perioperative evaluation represents an opportunity to identify patients who meet National Cholesterol Education Program criteria and impact their long-term outcome.

1. Statins should be continued in patients who are already on statin therapy and undergoing noncardiac surgery.
2. For patients undergoing vascular surgery, it is reasonable to be on statin therapy.
3. Statins may be considered for patients with at least one clinical risk factor who are undergoing intermediate-risk surgery.

X. ANESTHETIC AGENTS AND PERIOPERATIVE HEMODYNAMIC MONITORING

A. Several studies have evaluated the effect of **anesthetic agents and techniques** on cardiac morbidity. It appears that there is **no one best myocardial protective agent.** All inhalational agents cause depression of myocardial contractility and afterload reduction, which can lead to hypotension. Several studies have suggested that **neuroaxial anesthesia (epidural and spinal)** may reduce pulmonary and thrombotic complications compared with general anesthesia. However, its role in lowering cardiac complications remains controversial. Decisions regarding anesthetic techniques are best left to the anesthesiologist. Perioperative pain management is important because it reduces postoperative catecholamine response and cardiac stress.

B. **Pulmonary artery catheters** are occasionally used in high-risk patients (advanced heart failure and severe CAD) who are undergoing procedures associated with significant hemodynamic stress. The ACC/AHA guidelines advise to assess the benefit versus risk when considering the use of pulmonary artery catheters. Catheter-guided volume optimization has no clear benefit perioperatively, and multicenter randomized trials have shown that pulmonary artery catheter use provides no benefit after noncardiac surgery or in the intensive care unit.

XI. POSTOPERATIVE MONITORING AND MANAGEMENT OF EVENTS

A. **Postoperative MI.** The pathophysiology of perioperative MI is not well defined and may be different from that of nonoperative MIs. Stress, inflammation, hypercoagulability, and hypoxia may all be contributing factors. The incidence of perioperative MI ranges from 2% to 6% in general. However, up to 50% of perioperative MIs may go unrecognized. The majority of perioperative MIs occur within the first 3 days after surgery, a period when the patients are receiving narcotics that could mask the pain, some patients are still intubated and sedated, and many of the clinical signs that patients normally manifest are attributable to other causes (e.g., hypovolemia, bleeding, and pain). Nonspecific findings, such as CHF, hypotension, nausea, or ST-segment depression, may be the only clues to postoperative ischemia. The prognosis of these unrecognized MIs is nevertheless similar to that of patients experiencing a recognized MI.

1. There are **no standard criteria for the diagnosis of perioperative MI in patients undergoing noncardiac surgery**.
2. **Troponin** is a more specific marker for perioperative MI than creatine kinase-myocardial band, which could be falsely positive after surgery.
3. **ECG and troponin** should be checked postoperatively in **patients with signs and symptoms suggestive of ischemia, but based on the current literature, routine measurement of troponin is not recommended after noncardiac surgery**.
4. It is also important to rule out **other causes for positive troponin, such as pulmonary embolism**.

5. Although there is an increase in use of intraoperative **transesophageal echocardiography** to monitor myocardial ischemia through wall motion abnormalities, there is insufficient information to make firm recommendations.
6. There are **no clear guidelines for the management of perioperative MIs. Identifying and treating correctible causes** is important (e.g., anemia and hypoxia). In general, primary PCI is preferred for **perioperative ST-elevation MI**. Although thrombolytic, antiplatelet, and anticoagulant therapies are beneficial in the treatment of non–ST-elevation MI or unstable angina in nonoperative setting, these therapies could potentially cause more harm than benefit in perioperative settings. Many drugs that are important in the long-term management of nonoperative MIs (e.g., aspirin, angiotensin-converting enzyme inhibitors, β-blockers, and statins) may not carry the same positive effect in perioperative MI patients. Large randomized clinical trials are needed to answer these questions.
7. Nonfatal perioperative MI is an independent risk factor for cardiovascular death and nonfatal MI during the 6 months following the surgery. Therefore, close follow-up with aggressive risk-factor modification is important for these patients.

B. The management of **postoperative heart failure and pulmonary edema** is not much different than in nonoperative settings. ECG and troponin should be checked to rule out MI.

C. Arrhythmias. Perioperative arrhythmias are common, especially among elderly patients and after thoracic surgeries. For patients with arrhythmias, the metabolic profile and medications should be reviewed, and any underlying reversible conditions should be corrected, including hypoxia, fever, bleeding, pain, and infection. β-Blockers and calcium channel blockers can reduce postoperative tachyarrhythmias.

1. Most **supraventricular tachycardias (SVTs)** necessitate rate control until the underlying cause is addressed. This can be achieved using β-blockers, calcium channel blockers, or digoxin. Adenosine can be effective in terminating certain reentrant tachycardias. New-onset **AF** raises embolic risk. To avoid the increased bleeding risk with anticoagulation after surgery, restoring sinus rhythm is often a preferred strategy. Rate control is advised and if the AF persists more than 24 hours, antiarrhythmic drugs could be used. Most AF will resolve within 36 to 48 hours, but if it persists, then anticoagulation is warranted. At any time if the SVT causes hemodynamic compromise or ongoing myocardial ischemia, electrical cardioversion is the therapy of choice.
2. Symptomatic **bradyarrhythmias** are managed with temporary pacing, and a permanent pacemaker can be implanted if and when indicated.

XII. POSTOPERATIVE MANAGEMENT. In most cases, the results of the preoperative evaluation determine whether a patient is at substantial cardiac risk. For these patients, postoperative care is dictated by the findings before the operation. In a few urgent cases, or for patients who did not undergo preoperative evaluation, postoperative evaluation and care are individualized.

A. After a patient has successfully undergone a procedure, the physician **assesses and manages risk factors** for coronary and peripheral atherosclerosis.

B. Management of risk factors, including smoking cessation, control of labile hypertension, aggressive management of hyperlipidemia, and glycemic control for patients with diabetes, is of paramount importance.

C. Particular attention is given to **patients who sustain perioperative MI or demonstrate perioperative ischemia** because these patients are at risk for recurrent MI or cardiac death in subsequent years. These patients should be followed closely and treated aggressively.

CHAPTER 35

Kia Afshar

Hypertensive Crisis

I. INTRODUCTION

A. Epidemiology. More than 50 million people in the United States are diagnosed with systemic hypertension, many of whom are inadequately treated. Approximately 1% of those poorly treated progress to a crisis phase, accounting for more than 50% of all cases of hypertensive crisis. Although the incidence is decreasing due to improved awareness, treatments, and public health measures, patients with untreated hypertension or suboptimal blood pressure control remain more susceptible to acute rises in blood pressure. Patients with secondary causes of hypertension are also at higher risk for hypertensive crisis. Unless promptly recognized and treated, hypertensive crisis can lead to acute central nervous system, renal and cardiovascular dysfunction, and, possibly, death. Effective and prompt antihypertensive treatment improves prognosis.

B. Definitions. Hypertensive crisis is defined as having either a **hypertensive emergency or hypertensive urgency**. According to the Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure, normal blood pressure is defined as a systolic blood pressure < 120 mm Hg and a diastolic blood pressure < 80 mm Hg. Severe hypertension is defined as a systolic blood pressure > 180 mm Hg and/or diastolic blood pressure > 120 mm Hg.

1. **Hypertensive emergency.** Hypertensive emergency is defined as **severe hypertension with evidence of acute end-organ damage,** which can be manifested by a variety of syndromes (Table 35.1). Severe hypertension in the presence of chronic organ damage without associated acute manifestations does not constitute an emergency. Delineating hypertensive emergency from urgency is important because it implicates the need for immediate parenteral blood pressure lowering therapy in a monitored setting (typically intensive care unit [ICU]) to minimize tissue damage and long-term complications. Delay may cause irreversible organ dysfunction and death.
2. **Hypertensive urgency.** Hypertensive urgency, on the other hand, is generally defined as **severe hypertension without acute end-organ damage**. In the absence of symptoms or acute organ dysfunction, severe hypertension can be lowered over a period of days to weeks. Patients can be treated with oral medications and usually managed as outpatients.
3. **Pseudoemergencies.** Pseudoemergencies are acute rises in blood pressure attributed to **a physiologic trigger, causing a massive sympathetic or catecholamine surge**. These are typically seen as the result of pain, hypoxia, hypercarbia, hypoglycemia, anxiety, or a postictal state. These scenarios must be differentiated from true hypertensive crises because the management differs significantly. Treatment is directed at the underlying trigger and does not necessarily include antihypertensive medications.

TABLE 35.1 Hypertensive Emergencies

Severe hypertension (> 180/120 mm Hg) with any of the following:
Encephalopathy
Acute stroke, intracranial hemorrhage, head trauma
Acute aortic dissection
Pulmonary edema
Myocardial ischemia and/or infarction
After coronary artery bypass surgery
Postoperative bleeding at vascular suture lines
Acute renal failure and/or hematuria and proteinuria
Retinal hemorrhages, exudates, papilledema
Eclampsia

II. PATHOPHYSIOLOGY

A. Autoregulation. Understanding autoregulation is the cornerstone of managing hypertensive crises safely while minimizing the risk of iatrogenic complications. The kidney, brain, fundi, and heart all possess **autoregulatory mechanisms that maintain blood flow at near-constant levels despite fluctuations in blood pressure**. This protects these vital organs from the consequences of hypoperfusion with decrease in blood pressure and hyperperfusion with increase in blood pressure. The cardiovascular equivalent to Ohm's law in physics ($I = V/R$) is that blood flow is equal to pressure divided by resistance. Constant blood flow is maintained by parallel changes in these two parameters: pressure and resistance. The endothelial layer in these vessels controls local autoregulatory vasoconstriction when the perfusion pressure increases and vasodilation when perfusion pressure decreases. There is a range of pressures for which the autoregulatory mechanism functions normally. In **normotensive patients** or in those with adequate hypertension management, this range of mean arterial pressures (MAPs) is approximately between 60 and 120 mm Hg. Loss of autoregulatory control at an MAP of 120 mm Hg in patients without preexisting chronic hypertension explains why a seemingly trivial elevation in blood pressure (160/100 mm Hg) can have severe end-organ damage. Classic examples of this phenomenon occur with acute illnesses such as acute glomerulonephritis, preeclampsia, and cocaine abuse. However, in **chronically hypertensive patients**, either undiagnosed or inadequately controlled, the autoregulatory range is shifted to the right from arteriolar smooth muscle hypertrophy. This hypertrophy minimizes the transmission of pressure to the capillary bed, allowing tissue tolerance of higher blood pressures, but at the same time places the patient at risk for hypoperfusion if treated to normotensive pressures (Fig. 35.1). **This is the reason that blood pressure should not be reduced too quickly in chronically hypertensive patients since this will result in relative hypotension causing tissue hypoperfusion**. Gradual reduction in blood pressure allows the rightward-shifted autoregulatory curve to normalize as the arteriolar hypertrophy slowly regresses. Treatment must be tempered by the fact that **abrupt overzealous blood pressure reduction may lead to hypoperfusion and ischemia, with potential for irreversible neurologic damage**. Cerebrovascular accidents, blindness, paralysis, coma, myocardial

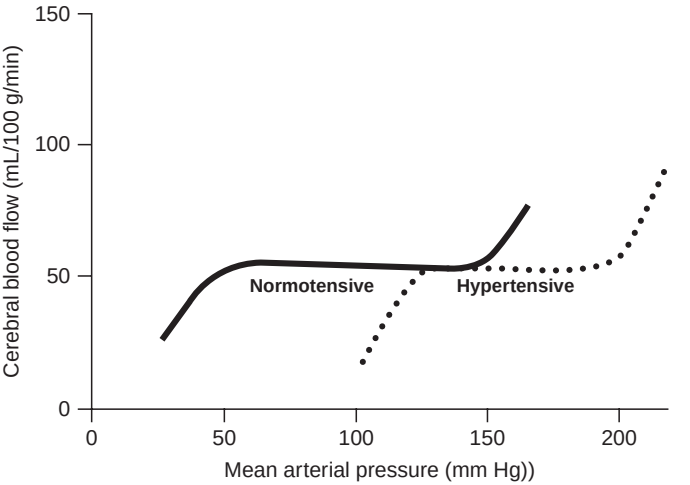

FIGURE 35.1 Autoregulatory cerebral blood flow response to changes in mean arterial pressure. Rightward shift of the autoregulation curve in chronically hypertensive patients. Adapted from Strandgaard S, Olesen J, Skinhoj, Lassen NA. Autoregulation of brain circulation in severe arterial hypertension. *BMJ.* 1973;1:507–510.

infarction (MI), and death have been reported as consequences of overaggressive blood pressure reduction.

B. Endothelial damage. Hypertensive emergencies are triggered by an abrupt increase in systemic vascular resistance (SVR) caused by elevated levels of circulating vasoconstrictors (e.g., norepinephrine and angiotensin II). The resultant increase in blood pressure leads to **arteriolar fibrinoid necrosis and endothelial damage**. This endothelial damage is the etiology of the loss of autoregulatory function. In addition, the necrotic fibrinoid debris causes narrowing and obliteration of the vascular lumen. Target organ dysfunction ensuing from these two processes causes further release of vasoactive substances, producing a cycle of increasing SVR, elevated systemic blood pressure, vascular injury, and tissue damage. This is the vicious cycle that propagates the hypertensive emergency.

C. Manifestations. The endothelial damage and escape from autoregulatory control during a hypertensive crisis leads to the classic acute end-organ complications. Because the brain is encased in a finite space in the skull, the excess blood flow results in cerebral edema and elevated intracranial pressure (ICP), leading to encephalopathy and seizures. In the kidney, the fibrinoid necrosis as well as the excess blood flow destroy glomeruli, resulting in proteinuria, hematuria, and acute renal failure. The acute injury to the fundi is manifested by exudates, hemorrhage, papilledema, and potentially blindness. The cardiovascular system can suffer from myocardial ischemia and pulmonary edema from the increased afterload state as well as aortic dissection and hemolysis from the shear stress.

III. ETIOLOGY. It is estimated that 30% to 40% of patients with a hypertensive crisis have an identifiable underlying cause compared with < 5% of those with hypertension who have not had a crisis. Evaluation for such secondary causes and precipitants is indicated in all patients with a hypertensive crisis.

TABLE 35.2 Conditions That May Precipitate a Hypertensive Crisis

Essential hypertension from undiagnosed or poorly controlled hypertension (most common)
Nonadherence to antihypertensive medication regimen
Renovascular disease
Acute, as well as chronic, renal parenchymal diseases
Acute central nervous system insults (e.g., ischemic stroke and intracranial hemorrhage)
Drug-induced (e.g., interactions, idiosyncratic reactions, exaggerated effects, and abrupt withdrawal)
Collagen vascular disease and vasculitis (classically scleroderma)
Preeclampsia
Pheochromocytoma
Obstructive sleep apnea

A. A common scenario is that of a patient inadequately treated for chronic hypertension or one that is medically nonadherent.

B. Risk factors for progression to hypertensive crisis include male gender, black race, low socioeconomic status, cigarette smoking or other tobacco abuse, and oral contraceptive use. Unlike primary hypertension, the incidence of which increases with age, the peak incidence of hypertensive crisis occurs among people aged 40 to 50 years.

C. Underlying pathologic states that can precipitate hypertensive crises include renal parenchymal disease, renovascular hypertension, collagen vascular disease and scleroderma, pheochromocytoma, vasculitis, preeclampsia, and neurologic disorders (Table 35.2).

D. A number of **medications and illicit drugs** can cause marked elevations in systemic blood pressure. The most common offenders are **cocaine**, oral contraceptives, sympathomimetic agents (e.g., diet pills and amphetamines), cold remedies (especially pseudoephedrine), nonsteroidal anti-inflammatory drugs (NSAIDs), tricyclic antidepressants, and monoamine oxidase inhibitors. Withdrawal from medications and illicit drugs can also precipitate severe hypertension. Examples include alcohol, benzodiazepine, and clonidine withdrawal.

IV. CLINICAL PRESENTATION

A. History

1. **Symptoms.** The history should focus on the organs that are known to suffer from end-organ damage: cardiovascular, neurologic, renal, and ocular. Cardiopulmonary symptoms include shortness of breath and chest pain. Neurologic symptoms include headache, confusion, lethargy, altered mental status, nausea, and vomiting. Oliguria and change in urine color to suggest hematuria may be the symptoms volunteered by the patient if there is renal damage. Blurred vision or change in vision suggests ocular involvement.
2. **Symptom chronology.** Among patients with severe hypertension, symptom chronology and the duration of uncontrolled blood pressure should be elicited, as this will guide the aggressiveness of blood pressure control.
3. **History of hypertension.** Most patients with hypertensive crises have an underlying history of chronic primary hypertension; however, a significant proportion have secondary forms of hypertension. Age of onset of hypertension as well as other potential clues to a secondary form of hypertension should be assessed.

4. **Contributory medication history** may include NSAIDs, oral contraceptives, erythropoietin, psychotropic agents, monoamine oxidase inhibitors, ephedrine, cyclosporine, tacrolimus, over-the-counter cold remedies, and many other medications. Withdrawal from clonidine is always a risk factor for a crisis in hypertensive patients to whom this medication has been previously prescribed. For those on antihypertensive medications it is crucial to elicit administration history, as a frequent, and potentially catastrophic, complication occurs when severe hypotension is induced by initiation of all outpatient medications in a patient with nonadherence.
5. **History of use of recreational drugs** such as **cocaine** and amphetamines, nonprescription stimulants including sympathomimetic weight loss pills, and performance-enhancing substances for athletes is important to elicit.
6. **Smoking history.** Smokers are at increased risk for progression to severe hypertension, perhaps due to endothelial dysfunction and dysfunctional autoregulation.

B. Physical findings

1. **Vital signs.** Blood pressure is measured in both upper and lower extremities to evaluate for stenosis or dissection of the aorta or great vessels. Severe hypertension is confirmed by taking two blood pressure measurements separated by 15 to 30 minutes. **No absolute level of blood pressure differentiates an emergency from an urgency.** ***The distinction is based upon the assessment of acute end-organ damage.***
2. **Optic fundi** are examined for signs of retinopathy, including exudates, hemorrhages, or papilledema.
3. **Neurologic assessment** is performed to assess mental status and neurologic motor deficits. Patients with hypertensive encephalopathy may manifest neurologic signs of confusion or seizure activity.
4. **Cardiovascular and pulmonary systems** are examined for the presence of an S_3, S_4, new murmur, and/or pulmonary edema. Total volume status should be assessed, as certain treatments can cause severe hypotension in the setting of volume depletion and other medications are less effective in the setting of fluid overload.
5. **Vascular system** is examined by palpation of pulses and auscultation for bruits, especially renal bruits.

V. DIAGNOSTIC EVALUATION. If a hypertensive emergency is suspected, appropriate arrangements for ICU admission and parenteral treatment should not be delayed while waiting for the results of further tests. Chest pain, shortness of breath, headache, blurred vision, signs of altered mental status, focal neurologic deficits, retinal exudates and hemorrhages, crackles, an S_3 gallop, and pulse deficits all point toward an emergency. Diagnostic testing can be performed after treatment has been instituted.

A. Complete blood count and blood smear. The presence of anemia with schistocytes should raise concerns for hemolysis and microangiopathic hemolytic anemia.

B. Blood chemistries to evaluate for renal function and electrolyte levels. Hypokalemia and other electrolyte disturbances may give a clue to a secondary cause of hypertension (e.g., primary hyperaldosteronism and Cushing's syndrome).

C. Urinalysis to look for proteinuria, hematuria, and casts. **Hematuria** and moderate to severe **proteinuria** are surrogate markers for glomerular damage.

D. Finger-stick glucose test should be performed to exclude hypoglycemia as the cause of altered mental status in the setting of suspected hypertensive encephalopathy as well as a cause of a pseudoemergency.

E. Electrocardiogram to evaluate for myocardial ischemia and chronicity of hypertension with evidence of left ventricular hypertrophy. **Cardiac markers** of ischemia (creatine kinase and troponin) should be checked but troponin is a very sensitive

marker and will commonly be slightly above the upper limit of normal in severely hypertensive patients. This, in isolation, should not be considered acute end-organ damage.

F. **Chest radiograph** assesses heart size, can confirm auscultatory findings of pulmonary edema, and may show a widened mediastinum to suggest an aortic dissection.

G. **Computed tomography and/or magnetic resonance imaging (MRI) of the brain** may be indicated to evaluate neurologic deficits and altered mental status, especially in the setting of suspected primary stroke, hemorrhage, or trauma.

H. A urinary **toxicology screen** should be collected, as cocaine and other illicit drugs frequently cause severe hypertension.

I. Prior to initiating treatment, especially in hypertensive urgencies, obtaining **renin and aldosterone** level measurements as well as serum and urine **metanephrine** samples assists with retrospective analysis for a secondary cause of hypertension. Many of the medications used to treat hypertension (β-blockers, diuretics, and angiotensin-converting enzyme [ACE] inhibitors) confound the interpretation of these tests. This diagnostic evaluation should never delay treatment of a patient presenting with hypertensive emergency.

J. After appropriate management and resolution of the crisis, work-up for common **secondary causes of hypertension should be performed**. Renovascular hypertension is very commonly seen in these patients. In addition, primary hyperaldosteronism, coarctation of the aorta, obstructive sleep apnea, and Cushing's syndrome are frequently undiagnosed and should be investigated if the particular patient has suggestive features.

VI. THERAPY. The presence of **acute or rapidly progressive end-organ damage, and not the absolute blood pressure reading, determines whether the situation is an emergency or an urgency**. This determination dictates the type of treatment (i.e., parenteral or oral) and the setting (i.e., ICU, hospital ward, or outpatient) in which it is implemented. Management of acute hypertensive syndromes should be tailored to each patient and based on the presence, absence, and type of end-organ damage. For example, a blood pressure of 130/90 mm Hg may represent a hypertensive emergency for a patient with an aortic dissection, whereas a blood pressure of 200/120 mm Hg for a patient with asymptomatic chronic hypertension without acute end-organ dysfunction does not necessitate emergent parenteral therapy. The appropriate diagnostic evaluation and therapeutic plan are also dictated by the different variations of hypertensive crisis. For example, a pregnant woman with preeclampsia, a man with acute pulmonary edema, and an elderly patient with hypertensive encephalopathy require different diagnostic and pharmacologic strategies.

A. **Hypertensive emergencies**

1. **Goals of therapy** include immediate but controlled reduction of the MAP. The pharmacologic characteristics and potential toxic side effects of antihypertensive agents must be understood and anticipated.
   a. Patients are **treated in an ICU**, where clinical status and vital signs can be constantly monitored with the aid of an intra-arterial line.
   b. **Blood pressure is reduced in a controlled and predictable manner**. It is recommended that **blood pressure be reduced initially by no more than 25% of MAP over minutes to hours**. After the first 24 hours, further reductions should occur over days to weeks in order to allow the autoregulatory mechanisms to reset. **Exceptions include aortic dissection, postoperative bleeding, and pulmonary edema, all of which demand more aggressive blood pressure reduction to prevent catastrophic complications**.
2. **Medical therapy.** A number of parenteral antihypertensive medications are available to manage hypertensive emergencies. Characteristics of an ideal agent include rapid onset and cessation of action, a predictable dose–response curve,

TABLE 35.3 Parenteral Medications Used to Manage Hypertensive Emergencies

Drug	Dosage	Onset/duration	Indications	Side effects
Nitroprusside sodium (Nipride, Nitropress)	Infusion: 0.25–10 µg/kg/min	Immediate/3–5 min	Most emergencies	Nausea, vomiting, sweating, thiocyanate, and cyanide poisoning
Nitroglycerin (a.k.a. glyceryl trinitrate) (Nitro-Bid)	Infusion: 5–200 µg/min	Immediate/3–5 min	Myocardial ischemia, myocardial infarction, left ventricular failure	Headache, methemoglobinemia, tolerance with prolonged infusion
Labetalol (Normodyne, Trandate)	Bolus: 20 mg/5 min until desired effect (max 80 mg) Infusion: 1–2 mg/min	5–10 min/1–8 h	Most emergencies except those complicated by left ventricular failure	Heart block, orthostatic hypotension
Nicardipine (Cardene)	Infusion: 5–15 mg/h	5–10 min/1–4 h	Most emergencies except those complicated by left ventricular failure	Reflex tachycardia, headache, nausea, flushing Avoid in heart failure
Clevidipine (Cleviprex)	Bolus: 1–2 mg/h with potential doubling every 90 s for desired effect	2–4 min/5–15 min	Most emergencies except those complicated by left ventricular failure	Avoid in heart failure
Phentolamine (Regitine)	Bolus: 5–15 mg IV Infusion: 0.2–5.0 mg/min	1–2 min/3–10 min	Pheochromocytoma crisis Crisis due to catecholamine excess	Tachycardia, headache, flushing
Hydralazine (Apresoline)	Bolus: 10–20 mg IV every 30 min until desired effect achieved or side effects occur	10–20 min/3–8 h	Eclampsia	Marked hypotension, tachycardia, flushing. Contraindicated in myocardial ischemia, aortic dissection, and elevated ICP
Enalaprilat (Vasotec IV)	1.25–5 mg every 6 h	15 min/6 h	Scleroderma crisis, left ventricular failure	Marked decreases in blood pressure in high-renin states, renal failure, hyperkalemia
Fenoldopam (Corlopam)	Infusion: 0.1–0.3 µg/kg/min	< 5 min/30 min	Most emergencies, renal insufficiency	Tachycardia, headache, nausea, flushing Caution with glaucoma

ICP, intracranial pressure.

and minimal side effects. Table 35.3 lists parenteral antihypertensive agents, dosages, side-effect profiles, and specific indications.

a. Sodium nitroprusside is the drug of choice for most hypertensive emergencies. This is due to its favorable hemodynamic profile, rapid onset, and rapid cessation of action. A potent, direct vascular smooth muscle relaxant, nitroprusside, decreases afterload and preload by means of dilating arterioles and increasing venous capacitance. Hemodynamic effects include a decrease in MAP, afterload, and preload; renal blood flow and renal function may improve if cardiac output improves. Although the direct cerebral vasodilation by nitroprusside may cause an adverse increase in cerebral perfusion, this is counteracted by a potent effect on MAP. Most patients with a neurologic crisis who need blood pressure control tolerate nitroprusside without a worsening of neurologic status. Unlike intravenous nitroglycerin, nitroprusside does not raise ICP or cause headaches. However, the theoretical possibility of an increase in cerebral blood flow as well as increased ICP must be kept in mind if there is further clinical deterioration despite a decrease in the MAP when using this agent.

(1) Administration. Sodium nitroprusside must be administered by constant intravenous infusion in an intensive care setting with invasive arterial blood pressure monitoring. It has a very rapid onset of action, and its effect ceases within 1 to 5 minutes of stopping the infusion.

(2) Side effects. Red blood cells and muscle cells metabolize nitroprusside to cyanide, which is converted to thiocyanate in the liver and excreted in the urine. **Thiocyanate levels rise in patients with renal insufficiency, and cyanide accumulates in patients with hepatic disease**. Signs of thiocyanate toxicity include nausea, vomiting, headache, fatigue, delirium, muscle spasms, tinnitus, and seizures. Monitoring for signs and symptoms of toxicity and maintaining thiocyanate levels at < 12 mg/dL allow safe use of nitroprusside. Thiocyanate toxicity is extremely rare in the extensive experience with nitroprusside at our institution.

b. Labetalol is useful in most hypertensive crises. The main disadvantage is its relatively long duration of action. Labetalol is an α-blocker and nonselective β-blocker. When given through continuous intravenous infusion, the relative β- to α-blocking effect of labetalol is 7:1.

(1) The **hemodynamic effects** of labetalol include a decrease in SVR, MAP, and heart rate and a decrease or no change in cardiac output. Cardiac output is often spared because the decrease in stroke volume from the β-blockade is offset by the decrease in afterload from the α-blockade. Labetalol has little direct effect on cerebral vasculature, does not increase ICP, and is **considered by some to be the drug of choice in situations characterized by markedly elevated ICP**. Labetalol begins to lower blood pressure within 5 minutes, and its effects can last 1 to 3 hours after cessation of the infusion.

(2) Contraindications. Labetalol is contraindicated for patients with acutely decompensated heart failure, cardiogenic shock, bradycardia, second- or third-degree heart block, and severe reactive airway disease known to be exacerbated by β-blockers.

c. Nitroglycerin is an important drug for managing hypertension in the setting of myocardial ischemia, acute MI, and acute cardiogenic pulmonary edema (ACPE). It is primarily a venodilator and has modest effects on afterload at high doses. The decrease in preload and afterload decreases myocardial oxygen demand. Nitroglycerin also dilates the epicardial coronary arteries, inhibits vasospasm, and favorably redistributes blood flow to the endocardium. **Nitroglycerin directly increases cerebral blood flow, raises ICP, and is not used in situations initially characterized by high ICP**.

Tachyphylaxis to nitroglycerin is well known and it is not uncommon for the blood pressure to rebound after prolonged administration. Headache is the most frequent side effect.

d. **Fenoldopam** is a selective peripheral dopamine-1-receptor agonist approved for the management of severe hypertension. Fenoldopam is an arterial vasodilator with a rapid onset of action and a relatively short half-life when administered intravenously. It may be of particular benefit in patients with renal insufficiency, as it has been shown to improve renal perfusion. Fenoldopam may cause reflex tachycardia, which can be blunted by the concomitant use of a β-blocker. Fenoldopam is contraindicated in patients with glaucoma, because it can increase intraocular pressure. It is a potent systemic vasodilator and is used primarily by anesthesiologists to control blood pressure intraoperatively.

e. **Nicardipine.** As a dihydropyridine calcium channel blocker, nicardipine inhibits vascular smooth muscle contraction but has little to no activity on the heart's atrioventricular or sinus nodes. It is particularly useful in the setting of postoperative hypertensive crises and neurological scenarios, as it does not raise ICP and directly reduces cerebral ischemia. It is contraindicated in advanced heart block, acute MI, and renal failure. It is administered via a continuous intravenous infusion. **Clevidipine** is a short-acting dihydropyridine calcium channel blocker administered as a continuous infusion that does not cause reflex tachycardia. Its benefit over nicardipine is that the half-life is shorter and thus relative hypotension can be reversed quickly with cessation of the infusion.

f. **Enalaprilat.** This is a short-acting intravenous ACE inhibitor that lowers blood pressure abruptly. It is not widely used in hypertensive emergencies, as it can precipitate hypotension, particularly in volume-depleted patients or those with renal artery stenosis. ACE inhibitors are first-line therapy for the management of scleroderma renal crisis.

g. **Hydralazine.** Although very commonly administered, the role of intravenous hydralazine in hypertensive emergency should be limited to the treatment of pregnant women with preeclampsia and eclampsia. Hydralazine is a direct arterial vasodilator with no effect on venous capacitance. It crosses the uteroplacental barrier but has minimal effects on the fetus. It is usually administered in intravenous boluses of 10 to 20 mg and has a long duration of action. Hydralazine decreases SVR, induces compensatory tachycardia, and increases ICP. It can exacerbate angina and is **contraindicated in the care of patients with ongoing coronary ischemia, aortic dissection, or increased ICP**.

h. **Clonidine.** Clonidine should be used primarily in cases where the cause of hypertensive emergency is clonidine withdrawal.

i. **Oral agents.** Once the blood pressure is controlled parenterally, switching to an oral regimen that benefits the patient in the long term, based on their particular comorbidities, is recommended. In chronically hypertensive patients, this usually requires at least two antihypertensive medications. Increasing the dose of existing medications or reinitiating therapy in nonadherent patients is appropriate.

3. **Management of specific emergencies**

a. **Neurologic emergencies.** Patients with neurologic findings and severe hypertension present a particular challenge. Neurologic emergencies can be the result of a hypertensive emergency that will then be exacerbated by the elevated blood pressure or the result of a primary neurologic insult that causes markedly elevated blood pressures to maintain necessary perfusion. One key differentiating point is that **neurologic alterations caused by severe hypertension are reversed when blood pressure is controlled**

appropriately, whereas primary neurologic disorders typically do not improve with blood pressure control.

(1) **Hypertensive encephalopathy.** This condition occurs when cerebral edema is induced by markedly elevated blood pressures that overwhelm the autoregulatory capabilities of the brain and is characterized by headache, irritability, and an altered state of consciousness. The treatment of choice is **sodium nitroprusside or labetalol**. Agents that depress the sensorium or increase ICP (i.e., intravenous nitroglycerin) should be avoided. Mental status will classically revert to normal within hours of blood pressure reduction. **If there is no improvement despite an appropriate decrease in blood pressure, the diagnosis must be reconsidered and concern should be for a primary neurologic insult causing secondary hypertension**. During the neurologic work-up, an MRI of the brain may reveal white matter edema in the parieto-occipital regions, termed reversible posterior leukoencephalopathy syndrome. Occasionally, hypertensive encephalopathy will manifest as seizures. Along with appropriate blood pressure control, concurrent anticonvulsive therapy to terminate active seizures is appropriate; however, chronic antiepileptic therapy is not necessarily indicated since treatment of the hypertension prevents further events.

(2) **Ischemic stroke.** Although hypertension is a risk factor for ischemic strokes, the management of hypertension in the setting of an acute stroke is controversial. The elevated blood pressure is thought to be protection from hypoperfusion due to vasodilation in the peri-ischemic regions. In general, patients should not be treated unless their blood pressure > 220/120 mm Hg or they have evidence of acute end-organ damage elsewhere (e.g., aortic dissection and myocardial ischemia). In addition, in those that are eligible for thrombolytic therapy, a blood pressure < 185/110 mm Hg is required. The goal reduction is 15% in the first 24 hours. Labetalol is the preferred agent, with calcium channel blockers being acceptable alternatives.

(3) **Intracranial hemorrhage.** Intracerebral hemorrhage and subarachnoid hemorrhage (SAH) are often associated with severe hypertension. Similar to an ischemic stroke, the increased blood pressure is thought to be protective. Due to the blood within the skull, ICP increases. In order to maintain the necessary cerebral perfusion pressure (CPP) of 60 to 80 mm Hg in the setting of elevated ICP, an increase in MAP is necessary (CPP = MAP – ICP). Neurology consultation along with neuroimaging and intracerebral pressure monitoring is frequently used to guide blood pressure management. Nimodipine is considered the standard of care for SAH, as it prevents vasospasm commonly seen in this condition.

b. **Cardiovascular emergencies.**

(1) **Aortic dissection.** As opposed to most other presentations of hypertensive emergency when appropriate care requires that blood pressure be normalized slowly, in the setting of an acute aortic dissection **blood pressure must be corrected immediately**. Patients with a **type A dissection** have a mortality rate of 1% per hour in the first 48 hours unless medical therapy is instituted rapidly and the patient is referred for **emergency surgical intervention**. In the setting of an uncomplicated **type B dissection, antihypertensive therapy** aimed at reducing vascular resistance and shear force on the vessel wall is the treatment of choice. Aortic dissections require decreased vascular shear force by means of reducing the inotropic state of the heart and the ratio of change in ventricular pressure to the change in time (dP/dt). **This should be accomplished via**

β-blockade prior to vasodilation in order to prevent reflex tachycardia and increases in d*P*/d*t*. **Aggressive blood pressure reduction** is indicated, even for patients with normal blood pressure, because shear force and afterload must be maximally reduced to prevent extension of the dissection and/or aortic rupture. A systolic blood pressure between 100 and 110 mm Hg (or lower if tolerated) with a heart rate between 50 and 60 beats per minute is the goal. Suspect hemopericardium with tamponade or aortic rupture if hypotension is present prior to initiating therapy. **Sodium nitroprusside with an intravenous β-blocker** (metoprolol) is the treatment of choice at our institution. Continuous infusion with labetalol is sometimes used due to its combined effects on myocardial contractility as well as SVR but the fixed β-blockade to α-blockade ratio makes independent titration of blood pressure and heart rate challenging. Fenoldopam, esmolol, and diltiazem infusions are options as well.

(2) **Acute cardiogenic pulmonary edema.** Often termed flash pulmonary edema, **ACPE due to severe hypertension** is best treated with **sodium nitroprusside or nitroglycerin**. Because of the pulmonary edema, a common reflexive action is to administer intravenous loop diuretics; however, this may have deleterious effects downstream. Accepting this seemingly paradoxical statement requires insight into the pathophysiology of pulmonary edema in this particular setting. The patients at risk for ACPE tend to be older in age with long-standing hypertension or diabetes, all of which impair diastolic function. The **acutely** elevated blood pressure results in left ventricular afterload mismatch; left ventricular end-diastolic pressure suddenly rises with concomitant elevation of the pulmonary venous pressure. On the pulmonary capillary level, increased Starling forces cause transcapillary leak and, ultimately, pulmonary edema. If the patient is euvolemic prior to the acute pressure change, then the pulmonary edema is due to maldistribution of the intravascular volume and not due to total body volume overload. Intravenous loop diuretics may have an initial beneficial venodilatory effect, but the subsequent volume depletion can cause future hemodynamic side effects. Thus, **treatment should be aimed at decreasing the acute pressure overload and afterload mismatch**, which will reverse the fluid shift in a time frame similar to the rate of decompensation. If nitroprusside or nitroglycerin infusions are not immediately available in this setting, **nitroglycerin tablets can be given sublingually** with repeated administration until goal blood pressure is achieved. Because the ACPE is often due to rapid onset of pressure overload and not due to chronically elevated blood pressure, normalization of the blood pressure in this hypertensive emergency is well tolerated without ischemic risks. It is not uncommon to see immediate relief of dyspnea and hypoxia in a patient with florid pulmonary edema once the blood pressure is lowered. β-Blockers and calcium channel blockers must be avoided in the decompensated state since the impaired inotropy and chronotropy will exacerbate the already afterload burdened ventricle.

(3) **Myocardial ischemia.** Preload, afterload, contractility, and heart rate determine myocardial oxygen consumption. Elevated blood pressure, and thus afterload, can induce ischemia from the increased oxygen demand. In addition, the significantly elevated blood pressure can rupture stable coronary plaques, resulting in an MI. Blood pressure reduction with nitroglycerin is the treatment of choice. Nitroprusside is added if further blood pressure reduction is required. Although the optimization of cardiac parameters is likely beneficial, it must not be forgotten

that **antiplatelet and antithrombotic therapies** are the mainstays of medical management of acute coronary syndromes. **Emergent reperfusion** is indicated in ST-elevation MIs. Heparin infusion should not be started with uncontrolled systolic blood pressures (190 mm Hg or greater), as the risk of intracerebral bleeding is significant.

(4) **Postoperative bleeding. Postoperative bleeding from vascular suture lines should be treated with immediate normalization of blood pressure, similar to an aortic dissection.** Parenteral treatment with sodium nitroprusside, nicardipine, or labetalol is preferred. **After coronary bypass grafting, nitroglycerin** is considered the initial drug of choice to maximize cardiac perfusion.

c. Pregnancy. In addition to delivery of the fetus and placenta in preeclampsia, **intravenous magnesium** therapy is the treatment of choice to prevent progression to eclampsia. Labetalol or hydralazine, combined with a β-blocker to prevent reflex tachycardia, can be used safely in pregnancy. ACE inhibitors and angiotensin receptor antagonists are contraindicated.

d. Pheochromocytoma. Phentolamine is an intravenous α-adrenergic blocker useful in cases of pheochromocytoma as it is effective in cases of catecholamine excess. β-Blockers should never be used in isolation because they can cause a paradoxical increase in blood pressure due to the effects of unopposed α-receptor stimulation from circulating catecholamines.

B. Hypertensive urgencies. Most patients diagnosed with hypertensive urgency actually have chronically severe hypertension and **are not in any immediate danger of progressing to hypertensive emergency**. They are often people with chronic hypertension who are suboptimally treated or nonadherent. As previously mentioned, the key to distinguishing hypertensive emergency from urgency is to assess whether there is evidence of acute end-organ damage.

1. Goal of therapy

a. Hypertensive urgencies can often be managed with **oral medication without admission to the hospital**. End-organ damage is not imminent, and blood pressure can be lowered modestly over a period of hours as long as adequate follow-up care is ensured. **The greatest danger lies in overtreating these patients and inciting hypotensive complications**. However, even in the absence of acute end-organ dysfunction, hospital admission should be considered for patients with a diastolic blood pressure > 140 mm Hg, those with a high risk of cardiovascular complications (known coronary disease or previous stroke), or those with uncertain outpatient follow-up.

b. Since hypertensive urgencies can have significant morbidity if treated aggressively, lower initial doses of antihypertensive medications are used to treat patients with known cerebrovascular disease or coronary artery disease or who are volume depleted. These patients tend to have exaggerated responses to drug therapy. In addition, they are also especially vulnerable to the effects of hypotension. Monitoring for 4 to 6 hours is necessary to judge treatment effect and to look for complications. Urgent follow-up care is mandatory within 24 to 48 hours. The outpatient goal is to normalize the blood pressure over the next 2 or 3 months.

2. Drug therapy. In adherent patients already prescribed with antihypertensive medications, increasing the dose of a current medication is usually sufficient. If initiation of a new agent is required, the choice should be a medication that benefits the patient in the long-term; therefore, underlying comorbidities should be taken into account. For example, ACE inhibitors would be best for those with diabetes, chronic kidney disease, or systolic dysfunction, and β-blockers for those known to have coronary artery disease or atrial fibrillation. Although considered a first-line agent for chronic hypertension, diuretics tend to have a

poor response in severe hypertension when given as a monotherapy. However, a long-acting dihydropyridine calcium channel blocker, β-blocker, or ACE inhibitor can be started in isolation. The medications commonly used for hypertensive urgencies include captopril, long-acting nifedipine, and oral labetalol, although many other adequate choices exist.

a. **Captopril.** Considered by some to be the drug of choice, captopril is a **fastest-acting oral ACE inhibitor**. At small doses, it rarely causes marked hypotension, although this potential exists in patients who are markedly volume depleted or who have renal artery stenosis. Captopril begins to work within 15 to 30 minutes of ingestion and the duration of activity is 4 to 6 hours. An initial dose of 6.25 mg should be given and if hypotension does not occur within 1 to 2 hours, the patient will tolerate doses of 12.5 to 25 mg three times daily.
b. **Nifedipine.** ***The short-acting and sublingual forms of nifedipine should not be used, as profound hypotension is easily precipitated.*** The long-acting form is a potent antihypertensive medication and should be initiated at 30 mg daily with uptitration as an outpatient. The onset of action is not as quick as labetalol or captopril but the daily dosing is favorable for adherence.
c. **Labetalol.** A combined α-blocker and β-blocker, labetalol, taken orally has a relative β-blocking to α-blocking effect of approximately 3:1. Dosage begins at 100 mg (taken orally twice daily) and is titrated to the desired response. The onset of action is 30 minutes to 2 hours after administration; the duration of action is 8 to 12 hours.

VII. PROGNOSIS. The prognosis of a patient with an untreated hypertensive crisis is poor. Before the introduction of effective antihypertensive agents, 1-year mortality exceeded 80% and 5-year mortality was approximately 99%. In the modern era of effective antihypertensive medications, 10-year survival has improved to 70%. Therefore, appropriate recognition of these clinical syndromes coupled with the treatment of blood pressure in a safe and controlled manner is paramount to significantly improving outcomes for these once mortal conditions.

Evaluation of Chest Pain in the Emergency Department

I. INTRODUCTION. Chest pain is one of the most common problems evaluated in the emergency department (ED).

A. Each year, approximately 5 million persons who arrive at an ED with chest pain are admitted to the hospital, mainly to an intensive care unit; 1.2 million of these patients are ultimately diagnosed with acute myocardial infarction (AMI). However, **2% to 4% of persons who arrive with chest discomfort and AMI are inappropriately discharged** to home. This error in diagnosing myocardial infarction (MI) is dangerous and costly. **Early recognition and treatment** are also important because time to treatment is the single most important factor in the management of ST-elevation MI.

B. **Rapid evaluation and risk stratification** of patients with chest pain are essential to identify life-threatening conditions and improve outcomes. Emergency treatment is initiated in the ED to minimize permanent myocardial damage and improve survival, especially in patients with MI. **The goal of treatment in ST-elevation MI** is to achieve reperfusion as soon as possible, either by primary percutaneous coronary intervention or by thrombolytic therapy. **Conversely, in patients with non–ST-elevation acute coronary syndrome (ACS), maintaining antegrade flow in the coronaries with prevention of distal embolization is important**. The Thrombolysis in Myocardial Infarction (TIMI) risk model is a validated mechanism to determine prognosis and guide therapy in patients with ACS. The model consists of seven variables, with one point for each variable: age > 65 years, three or more risk factors for heart disease, known coronary stenosis, multiple anginal episodes in the last 24 hours, use of aspirin in the last week, electrocardiographic changes, and elevated cardiac biomarkers (Table 36.1). **High-risk patients** are typically admitted to a coronary care unit for management with antiplatelet and antithrombotic therapies. Urgent (within hours) cardiac catheterization and appropriate revascularization are recommended in these patients. **Intermediate-risk angina patients** are directed to a monitored telemetry unit and undergo further risk stratification such as stress testing and assessment of left ventricular function with possible cardiac catheterization. **The lowest risk patients** can be observed in a chest pain unit or discharged directly to home, depending on the clinical situation.

C. **Assessment** of chest pain in ED involves careful patient **history, physical examination, and 12-lead electrocardiogram (ECG)**. Functional stress tests can supply additional data, but the data are not immediately available, and triage decisions are often made without them. With clinical history, physical examination, and initial ECG, 92% to 98% of cases of AMI and approximately 90% of cases of unstable angina can be identified.

TABLE 36.1 Rate of Complications in Non–ST-Segment ACS Based on TIMI Risk Score

# risk factors	0–1	1	3	4	6	6–7
N patients	85	339	627	573	267	66
% total patients	4.3	17.3	32	29.3	13.6	3.4

II. CLINICAL PRESENTATION

A. History

1. **Chest pain.** The initial history should accurately characterize the location and duration of the patient's discomfort, associated symptoms, and aggravating and alleviating factors (Table 36.2). Most patients with ischemic chest pain describe it as substernal pressure, squeezing feeling, or a sensation of suffocation. Some patients describe it as aching, burning, or tightness. The pain may radiate to the shoulder, neck, jaw, left or right arm, and the fingertips. Occasionally, the pain may be predominantly epigastric or interscapular.
2. **Atypical presentations.** Dyspnea is often associated with chest pain during an MI. **Dyspnea** may also be the only major presenting symptom in about 10% of patients with MI. Other atypical presentations include fatigue, syncope, altered sensorium, stroke, nausea or vomiting, and lethargy. **Atypical presentations of AMI are more common in the elderly, in patients with diabetes, and in women**.
3. **Risk factors.** Although several clinical factors have been associated with an increased risk of cardiovascular disease, only the **age** of patient, **history of coronary artery disease,** and **male** sex are predictive of ACS among patients with chest pain. In some studies, diabetes and family history have been associated with ACS, but the overall power of these risk factors in predicting an ischemic event is low. The **absence of risk factors cannot be used to exclude cardiac ischemia**.

B. Physical examination

1. The physical examination helps to identify **signs of left ventricular dysfunction and occult valvular heart disease**. The presence of a third heart sound (S_3 gallop), rales, sinus tachycardia, hypotension, and increased jugular venous distention is associated with adverse outcome. The presence of these signs and symptoms indicates cardiac origin of the chest pain. A thorough physical examination also helps identify the cause of nonischemic chest pain. Chest wall tenderness, skin lesions, and pleural or pericardial rub can be useful in this regard.

TABLE 36.2 Differentiating Cardiac from Noncardiac Chest Pain

Favoring ischemic origin	Favoring nonischemic origin
Character of pain	
Squeezing	Sharp, knifelike
Burning	Stabbing
Heaviness	Aggravated by respiration
Location of pain	
Substernal	Left submammary area
Across mid-thorax	Left hemithorax
Radiation to the arms, shoulders, neck, head, forearms, interscapular region	Discomfort localized with one finger
Associated with nausea, vomiting, diaphoresis	Back pain that suggests aortic dissection
Factors provoking pain	
Exercise	Pain after completion of exercise
Excitement	Pain relieved by exercise
Stress	Provoked by a specific body motion
Cold weather	
Duration of chest pain	
Minutes	Seconds
	Hours without evidence of myocardial damage

From Selzer A. *Principles and Practice of Clinical Cardiology.* 2nd ed. Philadelphia, PA: WB Saunders; 1983:17, with permission.

2. **Response to treatment is not reliable** in unraveling the cause of chest pain. **Pain relief after administration of nitroglycerin does not necessarily point to MI or unstable angina, as other etiologies for chest pain are relieved with nitroglycerin**.

III. DIAGNOSTIC TESTING

A. The **ECG** is integral to the evaluation of chest pain and has important diagnostic and prognostic value. It is even more important in the evaluation of persons with diabetes and elderly persons who tend to have atypical symptoms.

1. Almost 50% of patients with MI have a normal or nondiagnostic ECG on presentation to the ED. **Sensitivity** depends on a number of factors, including the time from symptom onset, coronary distribution of ischemia, baseline ECG abnormalities, and patient characteristics. Electrocardiographic findings should normalize rapidly after resolution of chest pain. The electrocardiographic findings of a patient who does not have active chest pain are difficult to interpret.

Circumflex distribution ischemia is notoriously silent on an ECG, as the posterolateral wall is underrepresented on a conventional 12-lead ECG.

2. Among patients with the ischemic type of chest discomfort, ST-segment elevation on an ECG has a specificity of approximately 90% and a sensitivity of approximately 50% for the diagnosis of AMI. Specificity decreases to 82% and sensitivity increases to 69% when ST-segment elevation or depression, Q waves, or left bundle branch block (LBBB) is used to define abnormal electrocardiographic findings.
3. The ECG can be used to identify a population of patients at low risk for MI. A normal ECG indicates < 3% risk for MI and < 6% risk for death in the following year. However, approximately one-third of patients with unstable angina may have a normal or equivocal ECG. The **ECG cannot be used alone to exclude ACS**.
4. Preexisting abnormalities, including left ventricular hypertrophy, LBBB, Q waves, preexcitation, and paced rhythms, make interpretation of the ECG difficult. Comparison of the initial ECG with a prior tracing is often helpful in this setting. Whether new or old, the presence of **LBBB is an adverse prognostic finding**. New LBBB suggests left anterior descending coronary artery ischemia or infarct. Preexisting LBBB alone defines a group of patients at high risk for cardiac morbidity and mortality. Although LBBB complicates the electrocardiographic diagnosis of AMI, criteria have been proposed for ascertaining whether a patient has AMI and LBBB from the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO I) database.

B. **Biochemical markers** of myocardial necrosis are used in conjunction with the clinical history and ECG to confirm the diagnosis of MI. Biochemical markers include cardiac **troponins, creatine kinase–myocardial band (CK-MB) isoenzyme, and myoglobin**. These markers, especially troponins, are sensitive and specific for myocardial injury and can provide important prognostic information.

1. **Serial blood samples** are collected over a 24-hour period to measure a temporal rise and fall for the diagnosis of MI. All biochemical markers follow a predictable pattern of release after the onset of myocardial injury.
2. An **ideal serum marker** is specific to myocardium, highly sensitive, and quantitative; the serum concentration is proportional to the amount of myocardial tissue injured. Furthermore, the levels have to increase rapidly to allow early diagnosis. None of the available markers are optimal for the diagnosis of ACS. In most cases, the combination of serial measurement of markers and interpretation of clinical data such as ischemic symptoms and ECG changes leads to the accurate diagnosis of ACS.
3. Enzymes such as aspartate aminotransferase, lactate dehydrogenase, and total CK are released from dying myocytes but are relatively nonspecific for cardiac tissue.
   a. **CK-MB is released into the circulation after myocardial cell death.** There is some evidence in animal models that CK-MB can be released with reversible myocardial injury. However, this has not been shown in humans.
      - Most studies have confirmed that serial measurement of CK-MB for the diagnosis of AMI has a sensitivity of approximately 92% with a specificity of 98%. The initial level of CK-MB, however, does not carry equal statistical weight and does not have sufficient negative predictive value to exclude MI when used in isolation. The CK-MB level can be increased with normal or minimally elevated total CK levels; however, the significance of this finding is debatable.

   b. **Myoglobin** is a small heme protein that is not specific to cardiac tissue. The use of myoglobin as a marker of myocardial necrosis does not carry the

specificity of CK-MB measurement. **The advantage of myoglobin as a marker lies in its release kinetics**. Myoglobin is released rapidly after myocardial injury, and serum levels are detectable within 1 to 2 hours of the onset of symptoms. Peak serum levels are reached within 4 to 5 hours after MI. Within 1 to 3 hours of MI, serum myoglobin determination has a sensitivity of 62% to 100% in the detection of myocardial damage. Because of its short half-life, measurement of myoglobin may not help confirm the diagnosis for patients who seek treatment late after symptom onset. The specificity is low when there is a substantial release of skeletal muscle myoglobin and in the setting of renal failure.

c. Troponins

- Cardiac troponins are **proteins that regulate the calcium-dependent interactions between actin and myosin**. This interaction results in myocyte contraction and relaxation. **Troponin T** is a myofibrillary protein and is a constituent of the contractile apparatus of cardiac muscle. Cardiac troponins, like CK-MB, can be found in the serum soon after injury, but concentrations remain elevated for as long as 2 weeks. Cardiac troponin T and troponin I are useful in the diagnosis of ACS and have been shown to be very sensitive and specific markers of myocardial cell injury.
- A large, prospective analysis from the Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO IIa) trial has provided important data on the **value of cardiac troponins for diagnosis and risk assessment**.
  - **(i)** Among patients who present within 12 hours of the onset of myocardial ischemia, elevated levels of **troponin T** (> 0.1 mg/mL) are associated with significantly higher mortality within 30 days. This is true for all ECG subgroups examined, including those with ST depression, ST elevation, T-wave inversion, LBBB, and paced rhythms. A quantitative relation has also been demonstrated between levels of cardiac troponin T and long-term clinical outcome.
  - **(ii)** **Troponin I** also has similar prognostic value. Among patients with unstable angina and non–Q-wave MI, elevated cardiac troponin I levels (> 0.4 ng/mL) are associated with significantly higher mortality.
  - **(iii)** **Bedside tests** for cardiac-specific troponins are **highly sensitive** for the early detection of myocardial cell injury in ACS. Qualitative and quantitative point-of-care tests for troponin T and troponin I are fast, yielding results that are reliable and accurate within a few minutes. **Negative test results have been associated with low risk** and allow rapid and safe discharge from the ED of patients with an episode of acute chest pain, as long as these tests are done at least 8 hours after the onset of chest pain.

d. Novel biomarkers. B-type natriuretic peptide and C-reactive protein (CRP) are predictive of risk in patients with ACS. Measuring these markers in combination with troponin or CK-MB may improve the short- and long-term risk stratification of ACS patients. **Plasma myeloperoxidase** levels are elevated in persons with angiographically documented coronary disease and within culprit lesions prone to plaque rupture. Recent studies have shown that elevated myeloperoxidase levels predict cardiac risk in patients presenting to the ED with chest pain, independently of the level of CRP, troponin T, and other markers of inflammation. However, these novel biomarkers have yet to become incorporated into clinical practice guidelines for chest pain or ACS management.

C. Imaging studies. Although clinical history, initial electrocardiographic findings, and biochemical markers have been combined to diagnose ACS with high sensitivity

and specificity, atypical presentations and equivocal electrocardiographic findings can make diagnosis challenging. Investigations aimed at overcoming these problems have focused on myocardial perfusion and functional imaging.

1. **Echocardiography.** Two-dimensional echocardiography provides valuable diagnostic data on ventricular function and regional wall motion abnormalities.
   a. Myocardial ischemia can cause abnormal segmental function of the myocardium manifested as impaired relaxation, hypokinesis, akinesis, or dyskinesia.
   b. Although echocardiography alone has moderate sensitivity in the diagnosis of MI, it may be a useful adjunctive test, especially after reperfusion therapy. Echocardiography serves an important role in risk stratification after MI through assessment of left ventricular function.
   c. Normal findings at echocardiography cannot be used reliably to rule out myocardial ischemia.
   d. Echocardiography can be crucial in the evaluation of complications of MI, such as ruptured papillary muscle, free wall rupture, or ventricular septal defect.
2. **Radionuclide perfusion imaging** is useful to quantify myocardium at risk. It is rarely used for the diagnosis of ACS because of poor accessibility and cost.
   a. **Thallium 201 scintigraphy** has been used to detect the areas of reduced or absent perfusion in AMI. Areas of myocardium with a negative scintigraphic image, indicating decreased myocardial uptake, can be demonstrated in ischemic or infarcted myocardium within 6 hours of symptom onset. The diagnostic utility of such imaging is limited by the so-called moment-in-time problem; perfusion defects may represent acutely ischemic myocardium or preexisting areas of scar tissue. Thallium 201 imaging has relatively poor specificity in women because of difficulties in distinguishing between breast attenuation and perfusion defects caused by coronary artery disease.
   b. **Technetium 99m sestamibi tomographic imaging** has the advantage that it does not redistribute after initial injection. This type of imaging allows definition of an initial ischemic zone that can be studied even after reperfusion. Technetium-derived image quality is also superior to that of thallium and allows quantification of regional and global ventricular function by gated image acquisition. Perfusion imaging with technetium 99m appears to have a sensitivity equivalent to that of thallium 201 imaging in defining myocardium at risk.
3. **Computed tomography (CT)**. Recently, several studies have evaluated the role of multislice detector coronary CT angiogram in patients presenting to the ED with chest pain. The greatest promise of coronary CT angiogram appears to be in low-risk patients with chest pain, in whom absence of coronary artery disease has been shown to have a very high negative predictive value for subsequent diagnosis of ACS and very low rate of major adverse cardiovascular events during follow-up. The main limitation of this technology lies in the inability to determine the physiologic significance of coronary lesions of intermediate severity. Multislice detector CT has also been studied as a tool that can simultaneously assess for ACS, aortic dissection, and pulmonary embolism (PE). This approach appears promising; however, its use in the ED cannot be advocated until its clinical utility has been validated.

D. Early exercise stress testing. In general, exercise stress testing can be safely performed to further risk-stratify patients who are considered to be at a low clinical risk for MI. Studies have shown that this approach is safe in patients who have a normal or nondiagnostic ECG and negative biochemical markers for myocardial necrosis assessed within 6 to 12 hours of presentation to the ED.

IV. DIFFERENTIAL DIAGNOSIS. Differentiating ischemic from nonischemic causes of chest pain can be difficult (Table 36.3). It has been estimated that more than 50% of patients

TABLE 36.3 Differential Diagnosis of the Causes of Acute Chest Pain

Cardiac	Aortic	Pulmonary	Gastrointestinal	Miscellaneous
Acute coronary syndrome	Aortic dissection	Pulmonary embolus	Esophageal spasm/reflux	Costochondritis
Coronary spasm	Penetrating aortic ulcer	Pneumothorax	Esophagitis	Cervical spondylosis and other compression neuropathies
Syndrome X, microvascular disease	Aortic aneurysm	Pneumonia/ pleuritis	Esophageal rupture	Herpes zoster
Myopericarditis				Panic disorder
Aortic stenosis Hypertrophic cardiomyopathy				Anxiety

initially admitted to the hospital with a diagnosis of unstable angina are later discharged with a noncardiac diagnosis. Given that there is symptom overlap among a number of clinical entities, in most diagnostic strategies, it is assumed that **chest pain is cardiac in origin until proven otherwise**. It is important to understand the clinical characteristics that represent the leading noncardiac causes of chest pain. Life-threatening causes of chest pain that can be confused with ACS include aortic dissection, pericarditis with cardiac tamponade, and pulmonary embolus.

A. Pericarditis (see Chapter 40) is often accompanied by substernal chest pain, but the **pain** is more likely to be pleuritic in character and aggravated by recumbency, deep inspiration, and swallowing. **Physical examination** may reveal a three-component pericardial friction rub. The **ECG** often reveals ST elevation in multiple leads without reciprocal changes, whereas PR-segment depression in leads other than aVR and V_1 is a more specific sign of pericarditis. It is important to recognize that **pericarditis may be a late presentation of MI**. Cardiac tamponade is characterized by hypotension, elevated jugular venous pressure, and muffled heart sounds (Beck's triad). In addition, the presence of pulsus paradoxus, defined as an abnormally large (> 10 mm Hg) decline in systolic blood pressure during inhalation, is a very helpful sign in cardiac tamponade and reflects exaggerated ventricular interdependence, the key pathophysiologic mechanism in this life-threatening condition. Prompt bedside echocardiography wherever possible is very useful in confirmation of the diagnosis as well as guidance for percutaneous pericardiocentesis.

B. Aortic dissection (see Chapter 26) requires **urgent** diagnosis because early surgical intervention reduces the high short-term mortality rate. The **chest pain** of aortic dissection is typically described as sudden, severe, and tearing pain that radiates to the back and interscapular areas, which is most intense at onset. **Examination** may reveal a difference in right and left arm blood pressures, pulse deficits, and focal neurologic deficits. Aortic dissection may also involve the aortic valve or coronary ostia. The latter may be associated with the diastolic murmur of aortic insufficiency, myocardial ischemia, and ST-segment elevation on **ECG**. Diagnosis is primarily made by transesophageal echocardiography, multislice contrast-enhanced CT, or magnetic resonance imaging. All these imaging modalities have high sensitivity and specificity in the diagnosis of acute aortic dissection. The preferred initial diagnostic imaging

modality should be based on availability, local expertise, clinical stability, and renal function. At our institution, CT is the initial test of choice in most cases of suspected acute aortic dissection.

C. Pulmonary embolism is potentially life threatening and can be associated with chest pain. The **chest pain** of PE is typically pleuritic in character and is associated with dyspnea and tachypnea. There is often a **history** of recent surgical intervention, malignant disease, or immobility. The cardinal **clinical findings** include hypoxia and tachycardia. An **ECG** may demonstrate right-axis deviation, right bundle branch block, or occasionally the classic $S_1Q_3T_3$ pattern. In patients with low or moderate pretest probability of PE, a D-dimer level < 500 ng/mL by qualitative enzyme-linked immunosorbent assay or semiquantitative latex agglutination excludes PE with a very high negative predictive value. Spiral CT with contrast (CT pulmonary angiography) is the main imaging modality for diagnosing acute PE with very high specificity. However, when imaging results are inconsistent with clinical suspicion, additional testing in the form of V/Q scan or lower extremity ultrasonography may be necessary.

V. CONCLUSIONS. The ED is where life-saving therapy is initiated in patients with ACSs. It is important to rapidly and accurately risk-stratify patients with suspected ACS. Many patients will present with noncardiac conditions for chest pain, some of which are life threatening. It is important for the ED practitioner to have a working diagnosis of the varied causes of chest pain. There is a spectrum of ACSs, which ranges from high risk to low risk. The highest risk patients require emergent reperfusion therapy, whereas lower risk patients can undergo urgent invasive therapy or further risk stratification. Such an understanding can help direct patient care most appropriately and improve important outcomes, including survival.

CHAPTER 37

Imran N. Ahmad

Cardiac Trauma

I. INTRODUCTION. Trauma represents the leading cause of death in males younger than 40 years in the United States. Cardiothoracic injuries are a primary or contributing factor in up to 75% of all traumatic deaths. Cardiac trauma occurs most commonly in the setting of motor vehicle accidents, interpersonal violence, cardiopulmonary resuscitation (CPR), falls from great heights, as well as sporting and industrial accidents. **Cardiac trauma can be easily overlooked in the presence of distracting injuries, as it can occur in the absence of chest pain or visible wounds.** Emergency department physicians lead the initial management, while contemporary trauma teams are typically led by surgical subspecialists. However, cardiologists play an important consultative role in the diagnosis and management of cardiac trauma.

- **A.** Cardiac trauma is divided into **blunt trauma** (i.e., motor vehicle accidents and falls) and **penetrating trauma** (i.e., primarily, knife and gunshot wounds).
- **B.** As many as 50% of people with cardiac injuries die in the field, but advances in diagnostic testing and surgical techniques have improved the prognosis of patients who reach emergency centers alive. Definitive management requires rapid mobilization of the surgical team and transport to the operating room.
- **C.** Initial attention is focused on the airway, breathing, and circulation, and the primary survey is performed according to the published Advanced Trauma Life Support (ATLS) guidelines. The cardiac physical examination should assess vital signs, peripheral pulses, murmurs, signs of heart failure, distended neck veins, and the presence of pulsus paradoxus. Routine laboratory evaluation should include cardiac

biomarkers, and a portable chest radiograph should be performed rapidly. **Transthoracic echocardiography (TTE) at the bedside is the preferred modality for the initial assessment of cardiac trauma**. Focused Assessment with Sonography for Trauma is a widely applied technique using bedside ultrasound to rapidly assess blunt trauma at multiple body sites, including the heart. An electrocardiogram (ECG) is indicated to evaluate for suspected coronary dissection or traumatic coronary thrombosis. The role for cardiac computerized tomography (CT) using intravenous contrast is expanding, and it remains the diagnostic study of choice to evaluate suspected trauma and/or dissection of the aorta and great vessels, along with transesophageal echocardiography (TEE).

II. BLUNT TRAUMA

A. Blunt cardiac trauma generally occurs in the setting of motor vehicle accidents, but it may also be related to falls, blows from blunt objects, or CPR.

B. Blunt trauma may injure the **pericardium**, **myocardium, valves or subvalvular apparatus**, **coronary arteries**, or the **great vessels.** The clinical presentation is generally one of **tamponade** or **hemorrhage**, depending on whether the pericardium is intact. Although hypotension and tachycardia are seen in both scenarios, tamponade is suggested by elevated neck veins, muffled heart sounds, and pulsus paradoxus and is easily confirmed by a bedside echocardiogram. A new murmur coupled with signs of heart failure should raise clinical suspicion for injury to the valves or subvalvular apparatus.

1. **Pericardium.** Increased shear forces during blunt trauma may lead to lacerations or tears in the pericardium. Clinically, the patient may experience pleuritic chest pain, and an ECG may reveal the typical findings of pericarditis. Management is with analgesics, although late cases of constriction occasionally develop after traumatic injury to the pericardium.
2. **Myocardium**
   a. **Myocardial rupture.** The myocardium can be injured by several mechanisms in sudden deceleration injuries. Compression between the sternum and the spinal column, as well as sudden overdistention with blood after abdominal injuries, may lead to myocardial rupture. The thin walls and large diameter of the right atrium predispose it to rupture, and **more than 50% of cases of cardiac rupture involve the right atrium**. The left atrium may be involved in as many as 25% of cases, with the remainder involving the thicker walled right and left ventricles. Most victims die immediately, but some series suggest that survival may approach 50% if patients arrive with intact vital signs. Management requires prompt thoracotomy and definitive surgical repair. Emergency pericardiocentesis is relatively contraindicated, as it can lead to reaccumulation and arrest, and is generally only considered as a desperate measure in an arresting patient when trained personnel are unavailable to perform a thoracotomy.
   b. **Myocardial contusion.** Blunt chest wall trauma may lead to focal injury and necrosis of cardiac myocytes, known as myocardial contusion. Definitive diagnosis is based on histology, and, therefore, the true incidence and clinical significance of myocardial contusion remain controversial. Patients may complain of precordial pain, but symptoms are usually difficult to interpret in the setting of chest wall trauma and associated injuries. A number of studies have investigated the use of ECG, cardiac enzymes, and TTE in diagnosing myocardial contusion, but none of these tests has been found to be sensitive or specific for the diagnosis. The ECG may be normal or may show nonspecific ST-T wave changes or findings consistent with pericarditis. Elevations in serum troponin levels and creatine kinase–myocardial band (CK-MB) isoenzymes are observed in some patients, but CK-MB may be masked by skeletal muscle CK-MM release, especially when total CK > 20,000 U/L.

TTE may reveal a small effusion or focal wall motion abnormalities. Patients with contusion are thought to be at increased risk for arrhythmic death during the recovery period, as the injured, inflamed myocardium behaves much like scar tissue as a substrate for slowed conduction and unidirectional block in the development of reentry cycles. However, findings on ECG, TTE, or laboratory tests are insensitive in predicting outcomes. From a practical standpoint, the diagnosis of cardiac contusion does not generally alter management, as treatment is mostly supportive care, observation, and analgesia. However, making the diagnosis should alert physicians to the potential for arrhythmias. Most centers perform a baseline ECG and monitor patients with blunt chest wall trauma for at least 12 hours before discharge.

3. **Valvular insufficiency.** Injury to cardiac valves, papillary muscles, or chordae tendineae during blunt cardiac trauma may lead to acute valvular regurgitation. A review of 546 autopsies after blunt trauma suggested that valvular injury may occur in as many as 9% of cases, with a slight increase in frequency in patients with preexisting valvular heart disease. The **aortic valve is most commonly involved**, followed in decreasing frequency by the mitral and tricuspid valves. A new murmur, hypotension, and fulminant pulmonary edema should suggest the diagnosis. The differential diagnosis of a new holosystolic murmur (occasionally with a new right bundle branch block or right-axis deviation on the ECG) should also include a traumatic ventricular septal defect. An emergency transthoracic echocardiogram and rapid transport to the operating room are generally required. Acute tricuspid regurgitation is generally well tolerated with lower extremity edema and fatigue as the presenting symptoms, although it occurs relatively rarely.
4. **Coronary arteries.** Blunt trauma occasionally leads to **thrombosis** or **dissection** of a coronary artery and subsequent myocardial infarction. In general, the prognosis after a traumatic myocardial infarction is better than that of the usual acute coronary syndrome because patients tend to be younger and have less atherosclerotic burden and less comorbidity. Nevertheless, patients with infarctions related to trauma are at risk for all the mechanical complications associated with atherosclerotic disease, such as left ventricular aneurysm or pseudoaneurysm formation, ischemic mitral regurgitation, and ventricular septal defect. In rare cases, blunt trauma contributes to the formation of an arteriovenous fistula between the coronary artery and another structure, such as the coronary sinus, great cardiac vein, right atrium, or right ventricle. Clinically, the patient may have a loud, widely radiating murmur, and ligation of the coronary artery or bypass surgery may be necessary.
5. **Commotio cordis.** Case reports of sudden cardiac death in children and adolescents after relatively low-impact chest wall trauma (most commonly, a baseball or hockey puck striking the chest) have received significant media attention in the past. The mechanism is unclear, but it appears that a blow to the chest during an electrically vulnerable period of cardiac repolarization may induce ventricular tachycardia or ventricular fibrillation. Victims have been surprisingly refractory to cardiac defibrillation, and few of them survive. Autopsy reports consistently show no evidence of underlying structural heart disease.
6. **Great vessels.** The aorta may also be injured in motor vehicle accidents and falls when sudden deceleration leads to tears or disruption of the vessel. Not surprisingly, most patients with aortic rupture die immediately, but 10% to 20% may reach emergency centers alive if the bleeding is limited by clot or by the pleura. Aortic rupture typically occurs at the proximal portion of the descending aorta, where the aorta is tethered against the spine by intercostal arteries and the ligamentum arteriosum. Patients frequently present with chest or back pain and hypotension, but a high index of suspicion is often needed to make the diagnosis. Increased pulse pressure in the upper extremities and diminished pulse pressure in the lower

extremities may be found on examination. The chest radiograph may reveal a widened mediastinum, large left pleural effusion, loss of the aortic knob contour, or deviation of the esophagus to the right. A normal chest radiograph, seen in as many as 25% of patients, does not rule out acute aortic pathology.

CT scan with intravenous contrast is generally the first-line imaging modality for the diagnosis of ascending aortic dissection and other suspected traumatic injury to the aorta. TEE is also useful and has the advantage that it can be performed rapidly at the bedside in a critically ill patient who is not suitable for transport. TEE requires sedation and may not be feasible in patients with maxillofacial or cervical spine injures. Although TTE cannot be used to exclude the diagnosis of aortic dissection, a limited and focused study can be performed more rapidly at the bedside than any other test, and visualization of a flap in the aortic root or ascending aorta can clinch the diagnosis. Magnetic resonance angiography is an alternative modality, but is not well suited for unstable patients due to the time required to perform the study. Aortography, once the gold standard, is now rarely performed out of concern for procedural complications in the setting of acute aortic injury. Definitive surgical repair is indicated for ascending aortic dissection or traumatic aortic rupture.

III. PENETRATING TRAUMA

A. Gunshot wounds and stabbings are the most common types of penetrating trauma. The prognosis depends entirely on the extent of injury and the number of chambers involved. Overall mortality is estimated at 60% to 93% for gunshot wounds, 22% to 62% for knife injuries, and 25% for bolting instruments (i.e., nail guns). Less frequently, iatrogenic catheter-induced injury can occur in the setting of temporary or permanent pacemaker placement.

B. As with blunt cardiac trauma, the clinical presentation tends to be one of **tamponade** or exsanguinating **hemorrhage**, depending on the integrity of the pericardium. **However, unlike in the case of blunt trauma, tamponade carries a favorable prognosis in penetrating trauma**. One series described a survival rate of 73% among patients with penetrating trauma with tamponade versus 11% among those without. Thrombus within the pericardium is thought to stabilize the rapid hemorrhagic shock associated with penetrating injuries. Pericardial lacerations may also seal spontaneously. Bleeding from the muscular, thicker walled left ventricle is also more likely to be self-limited, whereas injury to the relatively thin right ventricle or right atrium is more likely to be catastrophic and fatal. Knife wounds tend to be smaller and focal, whereas gunshot wounds tend to be larger, extensive, and more likely to present with frank hemorrhage.

C. **The right ventricle is the chamber most often involved in penetrating trauma** because of its anterior location in the chest. As described for blunt trauma, penetrating trauma may result in laceration of the pericardium or myocardium, valves, coronary arteries, or the aorta.

D. **Diagnosis.** In an unstable patient, a TTE should be obtained rapidly at the bedside. Although images may be suboptimal, both the sensitivity and the specificity of TTE for identifying cardiac abnormalities in this setting are 85% to 90%. A portable chest radiograph may reveal the presence of a pneumothorax or hemothorax.

E. **Management.** After the diagnosis of penetrating cardiac trauma has been made, the patient should be transported as rapidly as possible to the operating room for definitive surgical repair. The infusion of saline and blood products should be continued as needed. Warming of fluids is often needed to prevent hypotherma associated with massive volume resuscitation. There is no role for serial pericardiocentesis in patients with trauma and pericardial effusion, but emergency pericardiocentesis is occasionally necessary if there are delays in reaching the operating room.

IV. SPECIAL CONSIDERATIONS

A. Indwelling foreign bodies and missile embolization. Missile embolization from bullet fragments, air gun pellets, or shrapnel is an extremely rare complication from gunshot wounds or battlefield injuries. Data from the Vietnam conflict suggest that this phenomenon complicates 0.3% to 0.4% of all vascular missile injuries. Clinical suspicion for embolization should be raised in a scenario of multiple penetrating entrance wounds or a single penetrating entrance wound without a corresponding exit wound. The majority of patients with right heart or pulmonary embolization are asymptomatic, but up to 17.4% of patients develop chest pain, dyspnea, or hemoptysis. Up to 4% of patients may exhibit cardiac arrhythmias. Patients with undiagnosed indwelling foreign bodies may also develop subacute bacterial endocarditis as a latent presentation. Metallic missile fragments are usually radiopaque and detected on plain x-rays or a noncontrast CT scan. Intracardiac indwelling foreign bodies should be evaluated by TEE, especially when endocarditis is suspected. Ultimately, the decision to remove asymptomatic indwelling foreign bodies is made on a case-by-case clinical basis considering operative logistics and weighing risk against the potential benefit.

B. Device implants. An awareness of device-related complications in the setting of cardiac trauma is important, given the expanding patient population with pacemakers and/or implantable defibrillators. Common complications in the setting of blunt trauma would include pocket hematoma, lead dislodgement, or fracture. Penetrating trauma could expose the generator and/or tunneled leads and lead to bleeding or secondary infection. Lead perforation is an uncommon but life-threatening complication manifested as tamponade. Hypotension and bradycardia should prompt concern for lead fracture or dislodgement, especially if the patient is known to be pacemaker dependent. Emergent transcutaneous or transvenous pacing is indicated if the underlying bradyarrhythmia is not hemodynamically tolerated. Device interrogation can also be performed at the bedside to assess pacer dependence and the functional status of all leads using computer equipment provided by the major manufacturers.

Pregnancy and Cardiovascular Disease

I. INTRODUCTION. Maternal cardiac disease is a major risk factor for nonobstetric mortality and morbidity in pregnant women. Substantial progress in the management of congenital heart disease has occurred over recent decades, so the majority of females born with heart defects now survive into their reproductive years. Advances in obstetrics have also enabled pregnancy in older mothers in whom hypertension and acquired heart disease are more prevalent and can pose challenges for the pregnancy. Rheumatic heart disease is less common than in the past, but is still encountered, especially in immigrant populations in the United States, and may manifest clinically for the first time in pregnancy. Cardiac disease has significant bearing on both maternal and fetal outcomes, and it is therefore essential that cardiologists and internists have a working knowledge of the impact of pregnancy on various cardiac diseases on pregnancy and can tailor management appropriately. In most cases, the presence of maternal heart disease does not preclude successful pregnancy, although thorough discussion and planning regarding risks and management strategies should begin prior to conception wherever possible.

II. NORMAL PHYSIOLOGIC CHANGES DURING PREGNANCY. A series of cardiocirculatory changes occur in pregnancy and peripartum. These changes **usually begin during the early first trimester** (5 to 8 weeks), peak in the late second trimester, and tend to plateau thereafter until the postpartum period. This second trimester peak in hemodynamic adaptations tends to correlate with the onset of clinical manifestations of cardiac complications during pregnancy.

A. The ***increase*** **in blood volume** during pregnancy is attributed to estrogen-mediated stimulation of the renin–aldosterone system, leading to salt and water retention along with various other maternal and placental hormones. **The plasma volume expansion varies from 20% to 100% and averages around 50%.** The relatively greater increase in plasma volume as compared with red blood cell mass leads to the physiologic anemia of pregnancy, which usually manifests around 30 weeks.

B. Cardiac output, stroke volume, and heart rate. Table 38.1 summarizes the changes in heart rate, stroke volume, and cardiac output. **The cardiac output is estimated to increase by approximately 30% to 50% above baseline.** The increase is attributed to higher preload as a result of increased blood volume, decreased systemic vascular resistance, and an increase in maternal heart rate by 10 to 15 beats/min. During the third trimester, stroke volume and cardiac output are dependent on body position and increase in the lateral position (particularly left lateral) and decline in the supine position due to compression of the inferior vena cava by the gravid uterus.

C. Blood pressure and systemic vascular resistance. The decline in systemic vascular resistance causes blood pressure to begin to fall in the first trimester and reach a nadir of about 10 mm Hg below baseline by the end of the second trimester. The pulse pressure widens due to the greater fall in diastolic blood pressure than in systolic pressure. As many as 11% of women develop the **uterocaval syndrome** of pregnancy, with a significant and symptomatic drop in blood pressure when lying supine

TABLE 38.1 Normal Hemodynamic Changes during Pregnancy and Postpartum Period

	Changes during different phases of pregnancy				
Hemodynamic parameter	**First trimester**	**Second trimester**	**Third trimester**	**Labor and delivery**	**Postpartum**
Heart rate	↑5–10%	↑10–15%	↑15–20%	↑20–30%	↓
Stroke volume	↑5–30%	↑30–40%	↓20–30%	↑300–500 mL with each contraction	↓
Cardiac output	↑5–30%	↑30–40%	↑> 40%	↑50%	Initial ↑ then ↓
Systolic BP	↔to ↓	↓	↔to ↑	↑	Baseline
Diastolic BP	↔to ↓	↓	↓to ↔	↑	Baseline
Systemic vascular resistance	↓10–30%	↓ 30–40%	↓ 30–40%	↑	Baseline

BP, blood pressure.

due to vena caval compression. **Weakening of the vascular walls** of the medium and large muscular arteries occurs because of decreased collagen deposition due to estrogen release and the effects of circulating elastase and relaxin. This makes pregnant women more susceptible to aortic dissection, especially in individuals with abnormally weak aortic tissue such as in Marfan syndrome. The addition of low-resistance vessels in the uteroplacental bed also contributes to the decrease in afterload.

D. A hypercoagulable state with decreased protein S, increased stasis, and venous hypertension is also observed.

E. Hemodynamic changes during labor and delivery. Each uterine contraction displaces about 300 to 500 mL of blood into the maternal general circulation (autotransfusion). There is an increase in stroke volume and heart rate, with cardiac output increasing by approximately 75% above baseline during contractions. Blood pressure and oxygen consumption also rise. The magnitude of these changes will be influenced by the mode of delivery—vaginal versus cesarean section—and also by the method of anesthesia and analgesia.

F. Hemodynamic changes postpartum. Despite the blood loss during delivery (averaging 300 to 400 mL for vaginal delivery and 500 to 800 mL for cesarean section), there is a **temporary increase in effective venous return due to the relief of caval compression and autotransfusion**. This may lead to an increase in stroke volume and cardiac output, resulting in augmentation in renal blood flow and a brisk diuresis. In women with preexisting cardiac disease, these rapid hemodynamic shifts may cause profound clinical deterioration. The hemodynamic changes associated with pregnancy usually persist for a few weeks postpartum and it may take up to 12 to 24 weeks for the parameters to return to their prepregnancy baseline.

III. CARDIOVASCULAR EVALUATION IN PREGNANCY

A. History. Fatigue, dyspnea, ankle swelling, and reduced exertional capacity are common in normal pregnancy and can mimic cardiac disease. Chest pain, orthopnea, or paroxysmal nocturnal dyspnea may represent cardiac pathology.

B. Physical examination. Table 38.2 highlights the important cardiac findings in normal pregnancy. Signs of jugular venous distention, displaced point of maximal

impulse, and peripheral edema are common in normal pregnancy. Normal auscultatory findings in pregnancy include exaggerated physiologic splitting of S_2, a physiologic S_3, a physiologic systolic murmur in the pulmonic area, and the continuous murmurs of "mammary soufflé" or a cervical venous hum. Examination findings that are not physiologic include an S_4, a loud systolic murmur, a purely diastolic murmur, and fixed splitting of S_2 or pulmonary crackles.

C. Noninvasive testing with echocardiography is considered safe in pregnancy and findings are as given in Table 38.2. Chest radiography should be performed only when absolutely necessary and with shielding of the pelvic area with protective lead. Magnetic resonance imaging is sometimes used for the diagnosis of cardiac disorders; its safety profile in pregnancy is unknown, and it should be avoided if possible.

TABLE 38.2 Findings in Normal Pregnancy

Symptoms
Fatigue
Dyspnea
Palpitations
Reduced exercise tolerance
Orthopnea
Lower extremity edema
Physical examination
Hyperventilation
Lower extremity edema
Distended neck veins with prominent *a* and *v* waves and brisk *x* and *y* descents
Increased heart rate and wide pulse pressure
Upward and leftward deviation of point of maximal impulse
"Flow" murmurs (pulmonic and aortic)
Mammary soufflé (left sternal border, continuous murmur)
Increased first heart sound and exaggerated splitting of second heart sound
Third heart sound
Electrocardiographic findings
Sinus tachycardia
Leftward axis deviation
Increased R/S ratio in leads V_1 and V_2
Repolarization changes
Echocardiographic findings
Increased left ventricular diastolic dimension
Increased left ventricular wall thickness
Mild increase in contractility
Moderate increase in size of right atrium, right ventricle, and left atrium
Functional pulmonary, tricuspid, and mitral regurgitation
Small pericardial effusion

D. Invasive testing with pulmonary artery catheterization (without fluoroscopy) can be utilized during pregnancy, labor, delivery, and the postpartum period for invasive monitoring and can be very useful for patients who suffer hemodynamic deterioration. Cardiac catheterization during pregnancy is rarely needed, except in the setting of acute myocardial infarction (MI) or to permit balloon valvuloplasty. Fluoroscopy and cine time should be minimized and direct irradiation to the fetus avoided. Vascular access from the arm rather than the leg is preferred whenever feasible.

IV. RISK ASSESSMENT AND GENERAL PRINCIPLES OF MANAGEMENT. One of the most important steps in managing a patient with heart disease who is considering pregnancy is to establish the level of maternal and fetal risk. This involves a multidisciplinary approach, with preconception counseling, contraception advice, and discussion of potential maternal and fetal acute and long-term morbidity and mortality. Baseline functional class, severity of cardiac disease, left ventricular function, and pulmonary pressures should guide the risk assessment. Table 38.3 delineates a stepwise approach for management of women with preexisting cardiac disease, and Table 38.4 lists high-risk predictors. **Maternal New York Heart Association (NYHA) class II symptoms or higher, left ventricular ejection fraction < 40% or left-sided obstruction** are factors known to be predictive of neonatal complications, including premature birth,

TABLE 38.3 Basic Management Principles for Pregnant Women with Valvular Heart Disease

Risk assessment

Preconception

- Thorough history of cardiac symptoms and arrhythmias
- Baseline exercise tolerance and functional class
- Baseline electrocardiogram and echocardiography with ventricular function and pulmonary pressures
- Detailed discussion with the patient about the potential risks to self and fetus

During pregnancy

- Follow-up evaluation at least once per trimester
- Close monitoring of new symptoms or change in functional class
- Serial echocardiography for development of any new symptoms or signs

Treatment

Preconception

- Effective and safe contraception until pregnancy is desired
- Consider valve repair or replacement, correction of anomaly prior to conception if pregnancy poses significant risk of worsening clinical status
- Adjust medications to prevent adverse fetal side effects

During pregnancy

- Minimize medication use to only those absolutely required and discontinue or replace medications contraindicated in pregnancy
- If symptoms worsen and if indicated, consider correction of anomaly or valve repair or replacement

(Continued)

TABLE 38.3 Basic Management Principles for Pregnant Women with Valvular Heart Disease (*Continued*)

Labor and delivery
Invasive monitoring as needed
Cesarean section for obstetric indication
Monitor for decompensated heart failure and pulmonary edema and treat accordingly
Postpartum
Adjust and optimize medications
Consider correction of anomaly or valve repair or replacement if indicated
Treat postpartum anemia
Counseling and contraception for future pregnancies

TABLE 38.4 Risk Predictors of Adverse Maternal and Fetal Outcomes

Prior cardiac events or medication
Prior arrhythmia
NYHA class II or higher, or cyanosis
Ejection fraction < 40%
Pulmonary hypertension (pulmonary artery systolic pressure > 50% systemic pressure)
Severe aortic stenosis (valve area < 1.5 cm^2, Doppler jet velocity > 4 m/s
Symptomatic or severe mitral stenosis
Severe aortic or mitral regurgitation with NYHA class III or IV symptoms
Hypertrophic obstructive cardiomyopathy
Maternal anticoagulation

intrauterine growth restriction, respiratory distress syndrome, and death. Formal risk prediction scores include Cardiac Disease in Pregnancy (CARPREG), which is composed of four clinical features (prior arrhythmia or cardiac event, NYHA functional class > II or cyanosis, left heart obstruction, systemic left ventricular dysfunction with LVEF < 40%) with maternal cardiac event rates of 5%, 27%, and 75% for 0, 1, and > 1 of the features, respectively, and the more recent ZAHARA predictors derived from a large population of congenital heart disease patients.

Management of the pregnant patient with heart disease is a team effort involving the patient's primary care physician, high-risk obstetric team, and cardiologist, with active participation of the patients. **Prophylactic intervention for cardiac lesions that significantly increase the risk of pregnancy should be performed where appropriate and feasible *before* pregnancy is contemplated**. Most patients with relatively low-risk cardiac conditions are successfully managed throughout pregnancy, labor, and delivery with conservative medical measures designed to optimize intravascular volume and systemic

loading conditions. Simple measures help, such as bed rest and avoidance of the supine position. Medications should be used judiciously and only when absolutely required during pregnancy. Drugs that are contraindicated in pregnancy should be discontinued before conception if pregnancy is contemplated. **In certain conditions such as cyanotic congenital heart disease, Eisenmenger syndrome, or severe pulmonary hypertension, pregnancy should be strongly discouraged, as patients with these conditions do not tolerate the hemodynamic changes of pregnancy**.

Specific lesions and their management in pregnancy are described later. The list, although extensive, is not complete, as a detailed description of every lesion is beyond the scope of this chapter.

V. PREGNANCY IN WOMEN WITH CONGENITAL HEART DISEASE. In general, patients with noncyanotic congenital heart disease have a better outcome with pregnancy compared with patients with cyanotic disease. Where applicable, patients should be made aware of the potential inheritability of the congenital disease. The 2007 American Heart Association (AHA) endocarditis guidelines do not recommend the use of prophylactic antibiotics for vaginal delivery, even in high-risk patients, such as those with complex congenital heart disease or surgically constructed systemic–pulmonary shunts. However, owing to the difficulty in predicting complicated deliveries and the potential complications of endocarditis, some authors still suggest antibiotic prophylaxis as reasonable for all patients with congenital heart disease, except in isolated secundum atrial septal defects (ASDs) and corrected patent ductus arteriosus (PDA). The 2008 American College of Cardiology/AHA (ACC/AHA) guidelines on the management of adults with congenital heart disease do suggest antibiotics at the time of membrane rupture prior to vaginal delivery for patients with prosthetic cardiac material or unrepaired/palliated cyanotic defects.

A. ASD and patent foramen ovale (PFO). Isolated ASD or PFO is usually well tolerated in pregnancy and considered low risk in general. Paradoxical pulmonary embolism during pregnancy has been reported. Ideally, an ASD with a significant shunt (> 1.5:1) should be corrected prior to pregnancy. Secundum ASD that is repaired prior to pregnancy is not associated with an increased risk of complications.

B. Ventricular septal defect (VSD). Isolated VSD without pulmonary hypertension is usually well tolerated during pregnancy, and correction of VSD prior to pregnancy and before development of pulmonary hypertension eliminates the risk. In pregnant patients with VSD and pulmonary hypertension, a drop in blood pressure during or after delivery can result in transient shunt reversal. This may be prevented by close monitoring of blood pressure, volume replacement, and the use of vasopressors, if necessary. VSD is commonly inheritable.

C. Patent ductus arteriosus. PDA without pulmonary hypertension usually has a favorable outcome. In patients with pulmonary hypertension, the management principles are similar to those with VSD.

D. Coarctation of aorta (COA). Coarctation, although usually associated with favorable outcomes, has been associated with severe hypertension, congestive heart failure, or aortic dissection during pregnancy. There is an association with congenitally bicuspid aortic valves (AVs). It is also associated with circle of Willis aneurysms, and cerebral hemorrhage from rupture of an aneurysm during pregnancy is possible. Limiting physical activity and controlling blood pressure may prevent complications such as cerebral hemorrhage and dissection. β-Blockers are usually the antihypertensive drugs of choice, although care should be taken not to lower the blood pressure excessively as this may compromise uteroplacental circulation. Significant COA with evidence of systemic hypertension, heart failure, or a peak gradient > 20 mm Hg should be corrected prior to pregnancy. Women who underwent prior surgical repair of a coarctation remain at risk for dissection, as the aortic wall is still abnormally weak. Correction of COA during pregnancy is indicated in patients with severe uncontrollable hypertension or heart failure and may be performed percutaneously.

E. Congenital aortic stenosis (AS). A congenitally bicuspid AV is one of the most common causes of AS. These patients should be screened for other cardiac malformations including COA. The details of management are described later in Section **VI**.

F. Pulmonic stenosis. Isolated pulmonic stenosis is usually well tolerated in pregnancy. It should be corrected prior to pregnancy if severe (peak gradient > 60 mm Hg). Percutaneous balloon valvotomy during pregnancy may be required in patients with severe right ventricular failure.

G. Ebstein anomaly. Noncyanotic Ebstein anomaly is usually well tolerated. Cyanotic patients are at very high risk for maternal heart failure and fetal prematurity or death. During labor and delivery, care should be taken to prevent a drop in blood pressure, and close hemodynamic monitoring is required along with rest, oxygen, and blood gas monitoring. It is sometimes associated with Wolff-Parkinson-White syndrome and pregnancy may precipitate supraventricular arrhythmias.

H. Tetralogy of Fallot (TOF). Women with TOF who have undergone successful repair during childhood with little or no residual outflow tract gradient, no pulmonary hypertension, and preserved ventricular function usually tolerate pregnancy well. In women with uncorrected or only partially corrected TOF, increased blood volume during pregnancy with increased venous return and decreased systemic vascular resistance may result in right to left shunt and cyanosis. A similar process may also occur with a fall in blood pressure during labor and delivery. **The outcome of pregnancy is very poor for both mother and fetus once cyanosis occurs**. It is also associated with high rates of premature labor, spontaneous abortion, and fetal growth restriction. The risk of a cardiac defect in the neonate ranges from 3% to 17%; genetic counseling and screening for the 22q11 deletion should be offered to women with TOF. Patients with residual lesions after partial correction such as pulmonic regurgitation, right ventricular outflow obstruction, and right ventricular dysfunction are at risk for heart failure and arrhythmia during pregnancy. Poor prognostic signs include maternal hematocrit above 60%, arterial oxygen saturation below 80%, right ventricular hypertension, and syncopal episodes. Patients with cyanotic disease should be strongly encouraged against pregnancy.

I. Eisenmenger syndrome. Pregnancy in women with Eisenmenger syndrome is associated with a very high maternal mortality in the range of 30% to 50%, with a 50% risk of fetal loss if the mother survives. Maternal death occurs mostly between the first few days to first few weeks following delivery due to rapid hemodynamic deterioration. Therefore, patients with Eisenmenger syndrome should be strongly discouraged against pregnancy. Early therapeutic abortion may be considered given the danger to the mother. If pregnancy is continued, close monitoring is necessary. Restricted physical activity, continuous oxygen use for at least the third trimester, and consideration of pulmonary vasodilating drugs are recommended. Due to increased incidence of thromboembolism, anticoagulant therapy is recommended, starting from the third trimester until 4 weeks postpartum. An attempt to shorten the second stage of labor by the use of forceps or vacuum should be made; cesarean delivery is associated with significantly higher mortality.

VI. VALVULAR HEART DISEASE AND PREGNANCY. Lesions generally associated with high maternal and/or fetal risks include symptomatic mitral stenosis (MS), severe AS (with or without symptoms), NYHA class III and IV symptoms with mitral or aortic regurgitation, valvular disease with severe pulmonary hypertension or left ventricular dysfunction, mechanical prosthetic valve requiring anticoagulation, Marfan syndrome, and hypertrophic cardiomyopathy (HCM). Lesions generally associated with low maternal or fetal risk include asymptomatic AS with normal ventricular function, mitral valve prolapse, mild MS, and NYHA functional class I or II mitral or aortic regurgitation.

A. Mitral stenosis. MS is one of the most common rheumatic valvular lesions seen in pregnancy and is poorly tolerated. The physiologic changes in pregnancy with increased blood volume and heart rate can lead to an increased pressure gradient across the valve and decreased filling time, respectively. This leads to increases in left atrial pressure and ensuing symptoms of pulmonary edema with dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. Occurrence of atrial fibrillation with a rapid ventricular rate often causes further clinical deterioration. Patients with moderate to severe MS are more susceptible to these hemodynamic disturbances. The rapid increase in venous return during labor and delivery may cause significant decompensation and requires very close monitoring.

Management depends upon the severity of stenosis, symptoms, and time of diagnosis. **If MS is diagnosed prior to pregnancy, patients with severe MS (valve area < 1 cm^2) or moderate symptomatic stenosis should be offered percutaneous mitral balloon valvuloplasty (PMBV) or valve repair if PMBV is not feasible, before pregnancy**. In patients with moderate asymptomatic stenosis, careful assessment of symptoms and exercise tolerance testing can help guide the decision for prepregnancy intervention. In patients with mild MS (valve area > 1.5 cm^2), pregnancy is usually tolerated with a favorable outcome. **Optimal management of an already pregnant patient with MS is aimed at reducing heart rate and left atrial pressure**. β-Blockers are the drug of choice, and selective β1-adrenergic drugs are preferred over nonselective β-blockers to avoid β2-adrenergic–mediated uterine relaxation. In patients with atrial fibrillation (Table 38.5), digoxin may also be used for ventricular rate control. Electrical cardioversion can be performed safely during pregnancy if the hemodynamic status warrants restoration of sinus rhythm. Left atrial pressure may be controlled by salt restriction and very judicious use of diuretics (excessive use can lead to reduced uteroplacental perfusion). In patients with symptoms and signs of clinical deterioration despite optimal medical therapy, PMBV may be necessary during pregnancy. This should be avoided in the first trimester if possible and proper abdominal and pelvic shielding must be used. Echocardiographic guidance by an experienced operator can limit radiation exposure. In cases with severe MS refractory to medical therapy and not amenable to PMBV, mitral valve repair or replacement may be considered. Cardiopulmonary bypass during pregnancy carries a risk of fetal demise and should be performed with normothermic perfusion and high flow volumes with the mother in the lateral decubitus position to maximize placental perfusion.

Most patients with MS can safely undergo vaginal delivery. Patients with symptomatic moderate and severe MS should have hemodynamic monitoring and optimization guided by pulmonary artery catheterization during labor and delivery

TABLE 38.5 ACC/AHA Guidelines for Management of Atrial Fibrillation in Pregnancy

Class I (benefits >>> risk) procedure/treatment should be performed/administered
Digoxin, a β-blocker, or a nondihydropyridine calcium channel antagonist is recommended to control the rate of ventricular response in pregnant patients with AF
Direct current cardioversion is recommended in pregnant patients who become hemodynamically unstable due to AF
Protection against thromboembolism is recommended throughout pregnancy for all patients with AF (except for those with lone AF and/or low thromboembolic risk). Therapy (anticoagulant or aspirin) should be chosen according to the stage of pregnancy

AF, atrial fibrillation.

and in the immediate postpartum period (12 to 24 hours) when relief of uterocaval obstruction can cause increased venous return and pulmonary edema. Epidural anesthesia is usually better tolerated than general anesthesia, and cesarean section is generally performed for obstetric indications only. Young pregnant women with a previous history of rheumatic carditis should continue to undergo penicillin prophylaxis postpartum as they did in the nonpregnant state.

B. Mitral regurgitation (MR). The most common cause of MR during pregnancy is either rheumatic heart disease or mitral valve prolapse. MR is usually well tolerated in pregnancy because the fall in systemic vascular resistance leads to a decreased left ventricular afterload. Atrial fibrillation and hypertension may sometimes cause acute symptomatic decompensation.

Asymptomatic patients are managed conservatively without any therapy, and patients with left ventricular dysfunction and decompensated heart failure are managed with diuretics and digoxin. In the peripartum period, increased venous return and systemic vascular resistance sometimes lead to decompensation requiring diuretics and afterload reduction. Angiotensin-converting enzyme inhibitors (ACE-Is) and angiotensin receptor blockers (ARBs) are contraindicated during pregnancy because of their teratogenic effect. Hydralazine may be used in patients with MR and hypertension for afterload reduction. Acute MR due to ruptured chordae is rare in pregnancy and is usually not well tolerated. It may require intraaortic balloon pump placement and emergent surgery.

C. Aortic stenosis. The most common etiology for AS in childbearing age is a congenitally bicuspid valve. Rheumatic AS is less common, but may occur in conjunction with MS. Mild-to-moderate AS with preserved left ventricular function is usually well tolerated during pregnancy. **Severe AS (i.e., AV area < 1.0 cm^2 and mean gradient > 50 mm Hg) significantly increases the risk during pregnancy and may lead to significant hemodynamic deterioration, heart failure, and premature delivery**. Patients with severe AS should therefore be counseled against pregnancy or undergo surgery prior to conception. Symptoms such as chest pain, syncope, or dyspnea usually present late in the second trimester or early in the third trimester. Patients with bicuspid AV and aortic root dilation, especially those with coarctation of the aorta, are at increased risk for spontaneous aortic dissection.

When severe symptomatic AS is diagnosed during pregnancy, PABV should be performed before labor and delivery. Although PABV may reduce the risk of decompensation in patients with severe AS, it has limited durability and only suffices as a temporizing measure until the patient can safely undergo AV replacement. Aortic insufficiency that occurs as a postprocedural complication of PABV is usually well tolerated during labor and delivery.

Close invasive hemodynamic monitoring, as in patients with MS, may be required. Spinal anesthesia and epidural anesthesia are discouraged during labor and delivery because of their vasodilatory effects.

D. Aortic regurgitation/aortic insufficiency (AI). AI is generally well tolerated in pregnancy due to the combination of reduced systemic vascular resistance and shortened diastole with the rise in heart rate. In a young woman, AI may be due to a congenitally bicuspid valve, an infective endocarditis, an autoimmune disorder (e.g., rheumatoid arthritis), or a dilated aortic annulus. Marfan syndrome should always be excluded due to its implications regarding aortic root stability. AI without left ventricular dysfunction is usually well tolerated in pregnancy owing to decreased systemic vascular resistance and increased heart rate causing a shorter diastole and therefore reducing regurgitation. In symptomatic patients with decompensated heart failure, diuretics, digoxin, and hydralazine may be used for afterload reduction.

E. Hypertrophic cardiomyopathy. Most asymptomatic patients with HCM have a favorable outcome during pregnancy. The overall morbidity and mortality with HCM and pregnancy is, however, still higher than that in the general population. Symptoms such as chest pain, palpitations, worsening dyspnea, and syncope may

occur and are more common in women who were symptomatic prior to pregnancy. Various arrhythmias, including supraventricular tachycardias, atrial fibrillation with hemodynamic deterioration and fetal distress, and ventricular fibrillation, have also been reported. There is an increased risk of fetal prematurity. Women should receive genetic counseling before conception whenever possible; the risk of inheriting the disease may approach 50% in certain familial forms of HCM.

Management depends on the presence of symptoms and the severity of left ventricular outflow obstruction. Blood loss, volume depletion, and vasodilators should be avoided, and medications should be reserved for symptoms of heart failure and arrhythmias. β-Blockers are usually the drug of choice for symptomatic patients. Patients with a history of syncope, life-threatening arrhythmias, or a family history of sudden cardiac death should be considered for prophylactic implantable defibrillators prior to pregnancy due to the potential arrhythmogenic effect of pregnancy.

Vaginal delivery is considered safe, but tocolytics with β-adrenergic properties and prostaglandins should be avoided. Epidural anesthesia is used with caution because of the peripheral vasodilatory effect, and excessive blood loss should be promptly repleted with fluids or blood transfusion. The brisk diuresis immediately postpartum may lead to a rapid decrease in intravascular volume and, therefore, a symptomatic increase in outflow tract gradient. This can be avoided by gentle intravenous (IV) hydration decreasing over 24 to 48 hours postpartum to achieve a euvolemic state.

F. Prosthetic heart valves. The selection of an appropriate prosthetic valve in a woman of childbearing age is controversial. **Where possible, the patient's own valve should be conserved or repaired. When valve replacement is necessary, bioprosthetic and homograft valves are safer for mother and child, although their use is associated with an increased risk of degeneration in younger people, which may also be accelerated by pregnancy**. Mechanical valves, and their anticoagulation requirement, confer increased maternal mortality, morbidity, and fetal loss. A detailed preconception discussion with the patient should include potential complications during pregnancy, the potential for harm to the fetus and/or mother with various anticoagulation strategies, and recognition of the signs and symptoms of valve dysfunction or heart failure. The risk of complication during pregnancy depends on the type of valve, position of the valve, and prepregnancy cardiac function and functional capacity. Patients with NYHA class III or IV symptoms should be strongly advised against pregnancy. In pregnant patients with well-functioning bioprosthetic valves, the management is similar to that in patients with native valves. Patients should be made aware of the possibility of valve degeneration and should be monitored for signs and symptoms of this.

Pregnancy should be discouraged in patients with mechanical heart valves. In pregnant patients with mechanical heart valves, management of anticoagulation is challenging. Pregnancy is a thrombogenic state, and thrombosis has been reported in up to 10% to 15% of patients with mechanical prosthetic valves during pregnancy. The incidence is particularly high in patients with older generation valves (Björk-Shirley and Starr-Edwards) in the mitral position, but complications and deaths have also been reported in newer generation valves in the aortic position. Patients with prosthetic valves and poor left ventricular function are also at risk for heart failure from volume overload during pregnancy and arrhythmias.

The management of anticoagulation during pregnancy is discussed in detail in a separate section of this chapter.

VII. OTHER CARDIOVASCULAR DISEASES AND PREGNANCY

A. Hypertensive disorders in pregnancy. Hypertensive disorders complicate 8% to 10% of pregnancies and are a major cause of maternal and perinatal morbidity and mortality. Hypertensive disorders can be broadly classified into chronic hypertension, gestational hypertension, and the preeclampsia–eclampsia spectrum.

Chronic hypertension is defined as blood pressure of 140/90 mm Hg or greater before pregnancy, before 20 weeks of gestation, or persisting beyond postpartum day 42. It is associated with increased maternal and fetal morbidity and elevates the risk of preeclampsia development. Blood pressure treatment is aimed at minimizing maternal end-organ damage (such as left ventricular hypertrophy, renal failure, or intracerebral hemorrhage), balanced against concerns that excessive pressure lowering may negatively impact fetal growth. The threshold for initiating drug therapy is controversial and differing recommendations are offered by the various international society guidelines.

Gestational hypertension is defined as hypertension induced by pregnancy and diagnosed after 20 weeks of gestation and usually resolving within 42 days postpartum. The major clinical task is vigilance in the detection of any features of preeclampsia, including development of significant new-onset proteinuria, an increase in preexisting proteinuria, or any suggestive symptoms. Gestational hypertension may portend the development of future primary hypertension and cardiovascular disease, but is otherwise usually associated with good maternal and fetal outcomes.

Preeclampsia occurs in 2% to 5% of all pregnancies, 10% of first pregnancies, and 20% to 25% of women with chronic hypertension. It can be diagnosed with a blood pressure above 140/90 mm Hg, proteinuria exceeding 300 mg per 24 hour urine collection (or > 30 mg/mmol in a spot urine sample), an increase in proteinuria or loss of blood pressure control in a woman with chronic hypertension, or the onset of headache, blurred vision, abdominal pain, transaminitis, or hypertension. However, rare cases occur without significant proteinuria or an elevated blood pressure. Onset is usually in the third trimester with resolution after delivery, although postpartum cases are reported. Risk factors include maternal age over 40 years, Black ethnicity, nulliparity, multiparity, first pregnancy with the male partner, prior hypertension or preeclampsia, obesity, diabetes, chronic kidney disease, thrombophilia, systemic lupus erythematosus, or a history of migraines. Patients with preeclampsia usually require hospitalization for IV magnesium sulfate to prevent seizures, bed rest, close fetal monitoring, and sometimes corticosteroids for acceleration of fetal lung maturity. The pathology involves aberrant invasion of myometrial arteries, resulting in unusually resistive spiral arteries and placental hypoperfusion. Although the etiology remains incompletely understood, angiogenic and antiangiogenic placental peptides (including PAPP-A, PlGF, sFlt-1, sEng, and PP-13) are providing insights into the pathophysiology of preeclampsia and may establish a diagnostic role as biomarkers.

Eclampsia is the development of grand mal seizures in a woman with preeclampsia. When preeclampsia is accompanied by poor prognostic features such as severe hypertension, **HELLP syndrome** (hemolysis, elevated liver enzymes, low platelets), placental abruption, cerebral hemorrhage, pulmonary edema, or renal failure, the fetus must be delivered immediately. Expert opinion supports delivery within 24 hours for women with treatment-resistant hypertension or maternal or fetal compromise, regardless of gestational age or fetal lung maturity. Beyond 34 weeks of gestation or in cases where fetal lung maturity has been achieved, delivery should occur without delay. Because of the high risk of maternal and fetal mortality and morbidity, these patients should be managed at a tertiary care center with high-risk obstetrics and neonatology.

Table 38.6 lists different drug therapies used to treat hypertension in pregnancy. IV labetalol is the drug of choice for acute hypertensive urgency or emergency in pregnancy. Hydralazine may also be used as a vasodilator. Sodium nitroprusside is usually avoided, especially in later stages of pregnancy, due to concern for fetal cyanide toxicity if used for more than 4 hours and should be used only as a last resort in cases where emergent control of blood pressure is required. **Methyldopa, labetalol, and nifedipine are the most commonly used oral antihypertensive agents during pregnancy, although there is a paucity of evidence for optimal blood pressure targets or drug choices**. It is generally agreed that **systolic blood pressures of 150 to 160 mm Hg and/or diastolic blood pressures of 100 to 100 mm Hg and above should be treated**.

TABLE 38.6 Drug Therapy for Hypertension in Pregnancy

Drugs for hypertensive urgency and emergencies			
Drug	**Mechanism of action**	**Dosing**	**Comments**
Labetalol	α–β-Adrenergic blocker	20–80 mg IV q10-20min (up to 300 mg)	Appears efficacious; widely used; scant safety data
Hydralazine	Vasodilator	5–10 mg IV q15-30min	Efficacious and safe during pregnancy and lactation
Sodium nitroprusside	Arterial-veno dilator	0.5–5.0 μg/kg/min	Concern for fetal thiocyanate toxicity
Drugs for long-term treatment of hypertension			
Drug	**Mechanism of action**	**Dosing**	**Comments**
Methyldopa	Central α_2-agonists	250 mg tid up to 4 g/d	Most commonly used; safety well established; drug of choice
Labetalol	α–β-Adrenergic blocker	100 mg tid up to 2,400 mg/d	Appears efficacious; widely used; scant safety data
Nifedipine	Calcium channel blocker	once daily sustained release dosing up to 120mg/d	Short-acting nifedipine may precipitate severe hypotension and should be avoided; hypotension also possible with sustained release

Adapted from Elkayam U. Pregnancy and cardiovascular disease. In: Braunwald E, ed. *Heart Disease: A Textbook of Cardiovascular Medicine.* 7th ed. Philadelphia, PA: Elsevier Saunders; 2005:1965–1982.

B. Marfan syndrome. Marfan syndrome is a connective tissue disorder resulting from mutations in the fibrillin gene. It is inherited in an autosomal-dominant fashion. The clinical manifestations include skeletal abnormalities, ectopia lentis, and cardiovascular abnormalities, such as aortic root dilation with or without aortic regurgitation, aortic dissection, and mitral valve prolapse. **Aortic dissection** and rupture are the most feared complications of pregnancy in patients with Marfan syndrome due to hormonal influence on aortic wall integrity. Dissection is more likely to occur during the **third trimester and during labor and delivery and peaks at 3 to 20 days postpartum**.

Screening echocardiography should be performed before pregnancy. **Enlargement of the aortic root to more than 4.0 to 4.5 cm elevates the risk of aortic dissection and rupture from moderate risk to high risk**. Elective repair of the aortic root before conception is strongly advised with a root dimension above 4.5 cm; management should be individualized in the range 4.0 to 4.5 cm. The aortic root should be monitored by serial echocardiography during pregnancy.

Medical management during pregnancy involves the use of **β-blockers** throughout pregnancy to reduce the risk of aortic rupture, careful control of blood pressure, adequate analgesia during labor and delivery, and consideration of general anesthesia and cesarean section at the time of delivery to maximize hemodynamic control. Women with Marfan syndrome without cardiac abnormalities have a low complication rate and can usually tolerate normal vaginal delivery with spinal or epidural anesthesia to minimize pain and hypertension.

C. Aortic dissection. Aortic dissection during pregnancy has been reported in women with Marfan syndrome, systemic hypertension, coarctation of the aorta,

Turner syndrome, and cocaine use. It occurs most commonly in the third trimester and the peripartum period. Transesophageal echocardiography is the key diagnostic tool, and a β-blocker is the preferred medication for management during pregnancy.

D. Coronary artery disease. **MI during pregnancy is rare**, occurring in 6.2 per 100,000 deliveries in the United States in 2000 to 2002. The possibility of MI should always be entertained in a pregnant or immediately postpartum woman, especially if her symptoms and electrocardiogram are suspicious for coronary ischemia. **Most MIs occur during the third trimester in older women who have had multiple prior pregnancies.** ***Coronary spasm, in situ coronary thrombosis, and coronary dissection are more frequently the underlying precipitants of MI*** than classic obstructive atherosclerosis. Acute MI may be the initial clinical manifestation of an underlying hypercoagulable state, such as the antiphospholipid antibody syndrome. The diagnosis and management of acute MI in the pregnant patient should follow the guidelines established for the general population.

Medical therapy for acute MI must be modified in the pregnant patient. Thrombolytic agents increase the risk of maternal hemorrhage substantially (8%). Low-dose aspirin, β-blockers, and nitrates are considered relatively safe. Short-term heparin administration has not been associated with increased maternal or fetal adverse effects. ACE-Is, ARBs, and statins are contraindicated during pregnancy; there is no established safety data for clopidogrel or glycoprotein IIb/IIIa inhibitors. Coronary angiography should be performed only when emergent angioplasty or coronary artery bypass grafting is anticipated during pregnancy and, if possible, avoided in the first trimester. In general, bare metal (rather than drug-eluting) stents should be used if percutaneous intervention is necessary during pregnancy, as clopidogrel will need to be discontinued peripartum.

E. Arrhythmias. The most frequent rhythm disturbances, premature atrial complexes and premature ventricular complexes, are not associated with adverse maternal or fetal outcomes and do not require antiarrhythmic drug therapy. Atrial fibrillation and atrial flutter are rare during pregnancy. Rate control may be achieved with digoxin and β-blockers. Direct current cardioversion may be performed safely during any stage of pregnancy. Anticoagulation is recommended for chronic atrial fibrillation in the setting of underlying structural heart disease. **Atrioventricular nodal reentrant tachycardia** is the most common supraventricular arrhythmia in pregnant and nonpregnant women. It can lead to hemodynamic deterioration in women with underlying heart disease owing to rapid rates. Adenosine may be administered safely to the pregnant patient for both diagnostic and therapeutic purposes.

Ventricular tachycardia (VT) is rare during pregnancy. It may, however, be the presenting manifestation of peripartum cardiomyopathy (PPCM). VT has also been associated with thyrotoxicosis and hyperemesis gravidarum. Most antiarrhythmic medications used to treat VT are safe during pregnancy, **except for amiodarone**, which should be used with extreme caution and only for arrhythmias not responding to other medications, as it may lead to **neonatal hypothyroidism**. Bradyarrhythmias are uncommon during pregnancy. Complete heart block may be acquired or congenital. Pacemaker support is not usually required, unless the bradyarrhythmia is symptomatic or causes hemodynamic deterioration.

F. Peripartum cardiomyopathy. This is defined as the development of idiopathic left ventricular systolic dysfunction in the last month of pregnancy or within 5 months of delivery, in the absence of any identifiable or preexisting cause of heart failure. The incidence of PPCM in the United States is estimated to be 1 in 3,000 to 4,000 live births and is **more common in women older than 30 years**. The following risk factors for PPCM have been proposed: **multiparity, history of preeclampsia, eclampsia, or postpartum hypertension, African descent, low socioeconomic status, or tocolytic therapy with β-agonists**. Symptoms include fatigue, dyspnea on exertion, orthopnea, nonspecific chest pain, peripheral edema, and abdominal discomfort

and distention. PPCM has long been regarded as an idiopathic disease, but recent research has implicated a 16 kDa protein produced from cleavage of prolactin under oxidative stress, which is observed in higher levels in patients with PPCM. Bromocriptine, which inhibits prolactin secretion, has been administered with favorable outcomes in a small series of patients with PPCM. Standard management of pregnant patients presenting with decompensated heart failure includes oxygen, diuretics, digoxin, and vasodilators. ACE-Is and ARBs are absolutely contraindicated in pregnancy but should be commenced postpartum.

The prognosis after development of PPCM is variable. **Approximately 50% of women completely recover normal heart size and function, usually within 6 months of delivery**. The remainder either experience stable left ventricular dysfunction or continue to experience clinical deterioration. Estimated maternal mortality ranges from 10% to 50%. Women with PPCM and **persistent left ventricular dysfunction**, **or whose left ventricular ejection fraction was below 25% at initial presentation**, are at **very high risk for complications in a subsequent gestation** and should be counseled to avoid further pregnancies. Patients with severe cardiac dysfunction and decompensation should be evaluated for cardiac transplantation or mechanical support after pregnancy.

G. Primary pulmonary hypertension. This is associated with **very high maternal mortality (30% to 40%) and poor fetal outcomes**. Worsening of symptoms occurs in the second and third trimesters, and death is usually from right ventricular failure or arrhythmias. Pregnancy should be strongly discouraged in patients with this diagnosis, and early therapeutic abortion should be considered for those who become pregnant. Anticoagulation throughout gestation, or at least during the third trimester, is recommended. Close hemodynamic monitoring during labor, delivery, and the early postpartum period is advised, and oxygen plus pulmonary vasodilators may be used.

H. Pregnancy after cardiac transplantation. Pregnancy after cardiac transplantation is considered high risk for the mother and fetus. Maternal morbidity is increased from hypertension, preeclampsia, renal failure, premature rupture of membranes, and infection. Fetal growth restriction and preterm labor are also a concern, along with potential adverse fetal effects of immunosuppressive medications. One study examined the outcomes of 47 pregnancies in 35 transplant recipients. There was no increase in maternal mortality in this study, but increased maternal morbidity, premature deliveries, and fetal growth restriction were observed.

VIII. MEDICATION CONSIDERATIONS IN PREGNANCY

A. Cardiovascular drugs. The most commonly used cardiovascular drug classes and their potential adverse effects during pregnancy are shown in Table 38.7.

B. Anticoagulation during pregnancy. Conditions requiring anticoagulation during pregnancy include mechanical prosthetic heart valves, chronic atrial fibrillation, acute venous thromboembolism, Eisenmenger syndrome, antiphospholipid antibody syndrome, and inherited deficiencies predisposing to thromboembolism (e.g., prothrombin gene mutation and factor V Leiden deficiency).

The three most common agents considered for use during pregnancy are **unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), and warfarin**. The Eighth American College of Chest Physicians Consensus Conference on Antithrombotic Therapy has recommended three potential strategies for anticoagulation during pregnancy (Fig. 38.1) and the 2008 ACC/AHA guidelines for the management of patients with valvular heart disease are summarized in Table 38.8.

The choice of anticoagulation regimens depends on the preferences of the patient and physician after consideration of the **maternal and fetal risks associated with the use of each drug**.

1. Warfarin. Warfarin freely crosses the placental barrier and can adversely affect fetal development. It has been associated with a high incidence of spontaneous

TABLE 38.7 Cardiovascular Drugs and Pregnancy

Drug	Indication	FDA category	Potential maternal or fetal side effects
Adenosine	Arrhythmia	C	Limited data on use
Amiodarone	Arrhythmia	D	Hyper/hypothyroidism, IUGR, congenital goiter
ACE-I/ARB	Hypertension	D	Contraindicated, IUGR, oligohydramnios, renal failure, fetal death
Aspirin	Coronary artery disease	D in third trimester	IUGR and bleeding in mother and neonate
β-Blockers	Arrhythmia, hypertension, MI, HOCM, hyperthyroidism, Marfan syndrome, mitral stenosis	C/D	Fetal bradycardia, hypoglycemia, IUGR (atenolol is category D and should be avoided due to greatest IUGR concerns)
Calcium channel blockers	Hypertension	C	Maternal hypotension causing fetal distress reported, potential tocolytic effects
Digoxin	Arrhythmia, heart failure	C	Possible low birth weight, prematurity, but generally considered safe
Dofetilide	Atrial fibrillation	C	Possibly teratogenic in animal studies
Diuretics (thiazides)	Hypertension	B	Hypovolemia and reduced uteroplacental blood flow
Flecainide	Arrhythmia	C	Fetal death; limited data
Hydralazine	Hypertension, heart failure	C	Possible hypospadias, neonatal thrombo-cytopenia, neonatal lupus like syndrome
Lidocaine	Arrhythmia	B	Neonatal CNS depression
Methyldopa	Hypertension	B	Longest safety record, avoid in women with potential for depression
Nitrates	Hypertension	C	Maternal hypotension causing fetal distress reported
Procainamide	Arrhythmia	C	No adverse effects reported in third trimester
Propafenone	Arrhythmia	C	Limited data
Quinidine	Arrhythmia	C	Neonatal thrombocytopenia, mild oxytocic effect
Sodium nitroprusside	Hypertension, aortic dissection	C	Fetal thiocyanate toxicity
Sotalol	Arrhythmia	B/D	Fetal bradycardia, IUGR; category D in second and third trimesters

FDA category: A, controlled studies show no risk; B, no evidence of risk in humans; C, risk cannot be ruled out; D, positive evidence of risk. IUGR, intrauterine growth restriction; ACE-I, angiotensin-converting enzyme inhibitors; ARB, angiotensin receptor blocker; MI, myocardial infarction; HOCM, hypertrophic obstructive cardiomyopathy; CNS, central nervous system.

Data retrieved from Micromedex 2.0 correct as of October 1, 2011.

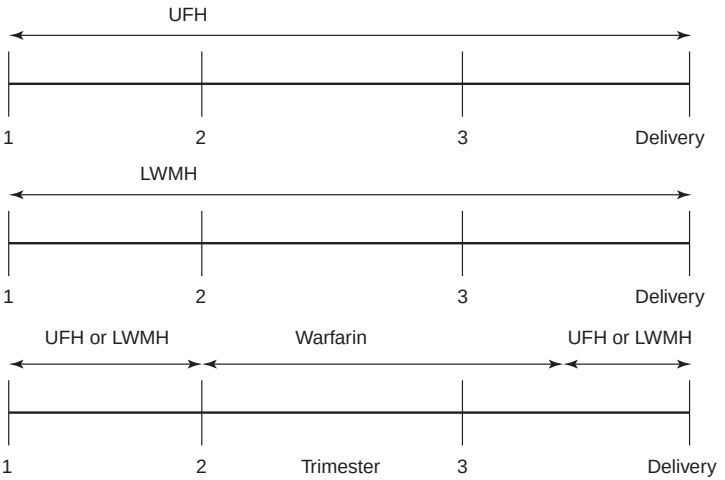

FIGURE 38.1 Anticoagulation options during pregnancy. UFH, unfractionated heparin; LMWH, low-molecular-weight heparin.

TABLE 38.8 ACC/AHA Guidelines for Selection of Anticoagulation Regimen in Pregnant Patients with Mechanical Prosthetic Valves

Class I (benefits >>> risk): procedure/treatment should be performed/administered	Level of evidence
All pregnant patients with mechanical prosthetic valves must receive continuous therapeutic anticoagulation with frequent monitoring	B
For women requiring long-term warfarin therapy who are attempting pregnancy, pregnancy tests should be monitored with discussions about subsequent anticoagulation therapy so that anticoagulation can be continued uninterrupted when pregnancy is achieved	C
Pregnant patients with mechanical prosthetic valves who elect to stop warfarin between weeks 6 and 12 of gestation should receive continuous intravenous UFH, dose-adjusted UFH, or dose-adjusted subcutaneous LMWH	C
For pregnant patients with mechanical prosthetic valves, up to 36 weeks of gestation, the therapeutic choice of continuous intravenous or dose-adjusted subcutaneous UFH, dose-adjusted LMWH, or warfarin should be discussed fully. If continuous intravenous UFH is used, the fetal risk is lower, but the maternal risks of prosthetic valve thrombosis, systemic embolization, infection, osteoporosis, and heparin-induced thrombocytopenia are relatively higher	C
In pregnant patients with mechanical prosthetic valves who receive dose-adjusted LMWH, the LMWH should be administered twice-daily subcutaneously to maintain the anti-Xa level between 0.7 and 1.2 U/mL 4 h after administration	C

(Continued)

TABLE 38.8 ACC/AHA Guidelines for Selection of Anticoagulation Regimen in Pregnant Patients with Mechanical Prosthetic Valves (*Continued*)

Class I (benefits >>> risk): procedure/treatment should be performed/administered	Level of evidence
In pregnant patients with mechanical prosthetic valves who receive dose-adjusted UFH, the aPTT should be at least twice the control	C
In pregnant patients with mechanical prosthetic valves who receive warfarin, the INR goal should be 3.0 (range 2.5–3.5)	C
In pregnant patients with mechanical prosthetic valves, warfarin should be discontinued and continuous intravenous UFH given starting 2–3 weeks before planned delivery	C
Class IIa (benefits >> risk): it is reasonable to perform procedure/administer treatment	
In patients with mechanical prosthetic valves, it is reasonable to avoid warfarin between weeks 6 and 12 of gestation owing to the high risk of fetal defects	C
In patients with mechanical prosthetic valves, it is reasonable to resume UFH 4–6 h after delivery and begin oral warfarin in the absence of significant bleeding	C
In patients with mechanical prosthetic valves, it is reasonable to give low-dose aspirin (75–100 mg/d) in the second and third trimesters of pregnancy in addition to anticoagulation with warfarin or heparin	C
Class III (risk ≥ benefits): procedure/treatment should not be performed/administered	
LMWH should not be administered to pregnant patients with mechanical prosthetic valves unless anti-Xa levels are monitored 4–6 h after administration	C
Dipyridamole should not be used instead of aspirin as an alternative antiplatelet agent in pregnant patients with mechanical prosthetic valves because of its harmful effects on the fetus	B

UFH, unfractionated heparin; LMWH, low-molecular-weight heparin; aPTT, activated partial thromboplastin time; INR, international normalized ratio.
Level of evidence: A, multiple population risk strata evaluated; B, limited population risk strata evaluated; C, very limited population risk strata evaluated.

Adapted from Bonow RO, Carabello BA, Chatterjee K, et al. 2008 focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease. *J Am Coll Cardiol.* 2008;52:e1–e142.

abortion, prematurity, still birth, and fetal bleeding. **The incidence of warfarin embryopathy (fetal bone and cartilage formation abnormalities) has been estimated at 4% to 10%; the risk is highest when warfarin is administered during the 6th through the 12th week of gestation.** The risks are dose-dependent, and women maintained on a daily dose of < 5 mg daily have the lowest risks. When administered during the second and third trimesters, warfarin has been associated with fetal central nervous system abnormalities, such as optic

atrophy, microencephaly, intellectual disability, spasticity, and hypotonia. Warfarin's anticoagulant effects are more potent in the fetus than in the mother due to lower fetal levels of the vitamin K–dependent clotting factors and can cause neonatal intracranial hemorrhage or a retroplacental hematoma. Warfarin is considered safe during breast-feeding. Women taking warfarin prior to pregnancy should be counseled regarding the harmful effects, and if pregnancy is contemplated then frequent pregnancy tests or switching to UFH or LMWH should be considered.

2. **Unfractionated heparin.** UFH does not cross the placenta, and unlike warfarin does not have the teratogenic effects, and is, therefore, considered safer. **It is, however, associated with maternal osteoporosis, hemorrhage, thrombocytopenia, or thrombosis (heparin-induced thrombocytopenia with thrombosis [HITT] syndrome), and a high incidence of thromboembolic events with older generation mechanical valves**. UFH may be administered parenterally or subcutaneously throughout pregnancy. Subcutaneous (SC) heparin use in patients with mechanical valve carries an increased risk of valve thrombosis. The appropriate dose of UFH is based on an activated partial thromboplastin time (aPTT) of 2 to 3 times the control level. High doses of UFH are often required to achieve the goal aPTT because of the hypercoagulable state associated with pregnancy. Parenteral infusions should be stopped 4 hours before a cesarean section. In the event of preterm labor, spontaneous hemorrhage, or significant bleeding during delivery, UFH may be reversed with protamine sulfate.
3. **Low-molecular-weight heparin. The use of LMWH during pregnancy remains controversial, as it has not been adequately studied**. Its advantages over UFH include a more predictable anticoagulant response and lower incidences of HITT and osteoporosis. It does not cross the placenta, and it may be safer to the fetus even though data in this regard are limited. A twice-daily dosing schedule should be used. During pregnancy the volume of distribution for LMWH changes, and it is essential to monitor anti-Xa levels. The 4-hour-post dose target anti-Xa level varies between 0.7 to 1.2 and 1.0 to 1.2 U/mL depending on the guidelines followed; the manufacturer's specific target range should also be consulted. Although existing data support the use of LMWH with deep venous thrombosis in pregnancy, the safety and efficacy of LMWH in pregnant patients with mechanical valves remain controversial. One LMWH carries a manufacturer's warning regarding the safety of LMWH in patients with mechanical heart valves, but the true incidence of valve thrombosis in pregnant patients receiving LMWH is unclear. Small studies continue to demonstrate individuals with catastrophic valve thrombosis despite therapeutic anti-Xa levels, further underlining the limitations of the LMWH strategy. However, retrospective auditing of pregnancies managed with LMWH versus warfarin strategies has shown better neonatal outcomes with the LMWH option.
   (1) Therefore, anticoagulation for mechanical valves during pregnancy is challenging. The choice of anticoagulant should be made after detailed discussion with the patient. Overall, warfarin is probably the safer option for the mother, whereas heparin is less likely to result in fetal harm. In the event of unplanned pregnancy in a patient on warfarin, it is advisable to change from warfarin to UFH or LMWH until 12 weeks and then resume warfarin until the 35th week if the patient is willing to take it, with careful monitoring of the international normalized ratio (INR). The 2011 European Society of Cardiology guidelines on the management of cardiovascular disease during pregnancy offer a class IIaC recommendation for considering continuation of warfarin during the first trimester if the warfarin dose required for therapeutic anticoagulation is < 5 mg/d, after patient information and consent. The ACC/AHA guidelines for selection of anticoagulation regimen in pregnant patients with mechanical prosthetic valves, updated in 2008, are presented in Table 38.8.

(2) In patients with a **mechanical heart valve with high risk of thrombosis** (first-generation prosthesis; e.g., Starr-Edwards, Björk-Shiley in mitral position, atrial fibrillation, and history of thromboembolism) one of the following algorithms may be used: Continuous IV UFH (aPTT 2.5 to 3.5 times) for 12 to 13 weeks followed by warfarin (INR 2.5 to 3.5 times) for up to 35 weeks followed by IV UFH (aPTT 2.5 to 3.5 times) until delivery **or** SC twice-daily LMWH (anti-Xa level 0.7 to 1.2 U/mL) for 12 to 13 weeks followed by warfarin (INR 2.5 to 3.5 times) for up to 35 weeks followed by IV UFH (aPTT of 2.5 to 3.5 times) or SC twice-daily LMWH (anti-Xa 0.7 to 1.2 U/mL).

(3) In patients with a **mechanical heart valve with relatively lower risk of thrombosis** (second-generation prosthesis; e.g., St. Jude Medical, Medtronic-Hall, and any mechanical prosthesis in aortic position) options include the following: SC twice-daily LMWH (anti-Xa 0.7 to 1.2 U/mL) or SC twice-daily UFH (aPTT 2.0 to 3.0 times) for 12 to 13 weeks followed by warfarin (INR 2.5 to 3.0 times) for up to 35 weeks followed by IV UFH (aPTT 2.0 to 3.0 times) or SC twice-daily LMWH (anti-Xa 0.7 to 1.2 U/mL) **or** SC twice-daily UFH or SC twice-daily LMWH throughout pregnancy (data supporting this algorithm are limited).

CHAPTER 39

Sachin S. Goel

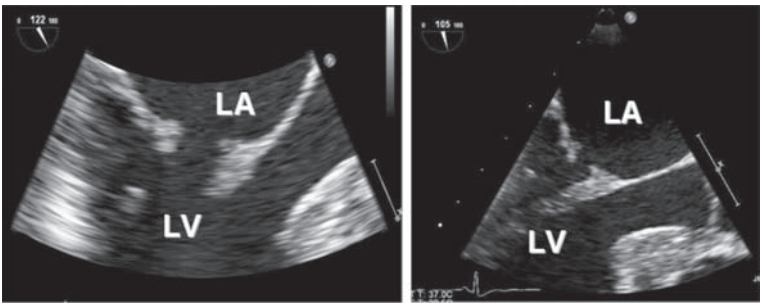
Cardiovascular Manifestations of Systemic Disease

Several systemic diseases involve the cardiovascular system, with important therapeutic and prognostic implications. It is vital for cardiologists to recognize, manage, and prevent cardiovascular involvement in various systemic diseases. This chapter reviews the cardiovascular manifestations of various systemic disorders.

I. RHEUMATOLOGIC DISORDERS

A. Rheumatoid arthritis (RA) is one of the commonest forms of chronic inflammatory polyarthritis resulting in joint destruction and deformation. It affects 1% to 3% of the population and is more common in women. It is characterized by chronic symmetrical polyarthritis that typically affects small joints of the hand, such as metacarpophalangeal and proximal interphalangeal joints, in addition to wrists and knees, and spares the thoracolumbar spine and distal interphalangeal joints. The most common cardiovascular manifestations of RA are as follows:

1. **Pericarditis** is very common and can be present in nearly 50% of patients with RA. It can vary from acute pericarditis and chronic asymptomatic effusive pericarditis to cardiac tamponade or chronic constrictive pericarditis, with significant hemodynamic consequences. Most cases with uncomplicated acute pericarditis will respond to nonsteroidal anti-inflammatory drugs (NSAIDs). Corticosteroid therapy may be needed for patients with severe pericarditis. Pericardiocentesis or surgical drainage may be required in cases of tamponade.
2. **Coronary artery disease (CAD)**. Patients with RA have increased mortality compared with the general population and the leading cause of death is cardiovascular disease. Patients with RA have accelerated atherosclerosis, likely a result of chronic systemic inflammation and use of corticosteroids. **After controlling for traditional risk factors of atherosclerosis, patients with RA have been shown to have two to three times greater risk of CAD compared with controls**. In the large prospective Nurses' Health Study, women with RA were found to have a twofold higher risk of myocardial infarction compared with controls. In addition to disease-modifying drugs to reduce systemic inflammation, aggressive lifestyle modification, including tight control of blood pressure and low-density lipoprotein cholesterol, seems warranted.
3. **Cardiomyopathy.** RA can cause granulomatous inflammation of the myocardium leading to cardiomyopathy or involve the conduction system resulting in varying degrees of heart block. Rarely, secondary amyloidosis can occur in RA, leading to an infiltrating cardiomyopathy.
4. **Valvular disease.** A small proportion of patients with RA can have valvular involvement in the form of rheumatoid nodules; however, clinically significant valve disease is very rare.



(A) (B)

FIGURE 39.1 Transesophageal echocardiogram demonstrating vegetations (Libman-Sacks endocarditis) on the atrial aspect of anterior and posterior mitral valve leaflets in a patient with systemic lupus erythematosus. Panel A is a zoom view of the valve leaflets whereas Panel B shows a less detailed image of the leaflets. LA, left atrium; LV, left ventricle.

B. Systemic lupus erythematosus (SLE) is a systemic autoimmune disease that occurs more commonly in women and is characterized by a wide range of organ involvement, including arthritis, dermatitis, glomerulonephritis, serositis, and hematologic abnormalities. Drug-induced lupus can occur with various cardiac medications, including procainamide, quinidine, and hydralazine, and this is associated with the development of anti-histone antibodies. SLE can affect the cardiovascular system in various ways:

1. **Valvular disease** is the most common type of cardiac involvement in SLE. The characteristic valvular lesions in SLE are nonmobile, noninfectious vegetations on the atrial aspect of the mitral valve or the arterial aspect of the aortic valve, referred to as Libman-Sacks endocarditis (Fig. 39.1). Studies have shown that valvular involvement is very common in SLE and occurs in > 50% of patients. The most common valvular abnormality is valvular thickening, followed by vegetations and valvular regurgitation or stenosis. Serial echocardiography should be performed to monitor for progression of valve disease. The vegetations can embolize and cause stroke or myocardial infarction in rare cases.
2. **Pericarditis** is very common in SLE and has been shown to occur in > 50% to 60% of patients. Associated pericardial effusion is usually exudative, with elevated protein and low glucose concentration, and infection must be ruled out in the setting of concomitant immunosuppressive therapy. Cardiac tamponade and chronic constrictive pericarditis can also occur.
3. **Coronary artery disease.** Premature coronary atherosclerosis has been shown to occur commonly in patients with SLE compared with age-matched controls. CAD can also manifest as coronary arteritis, thrombosis in the presence of antiphospholipid antibody syndrome (APLA—see Section **I.C**) or, rarely, embolism from Libman-Sacks endocarditis.
4. **Myocardial dysfunction** in patients with SLE can result from ischemia, valve disease, or long-standing hypertension. Patients with peripheral skeletal myositis have an increased risk of lupus myocarditis.
5. **Conduction system disease** with complete heart block can occur in infants born to mothers with SLE, particularly those with anti-Ro and anti-La antibodies. Women with SLE contemplating pregnancy should undergo screening for these antibodies prior to pregnancy and, if present, should undergo fetal echocardiography to screen for conduction abnormalities and myocardial dysfunction. There is some evidence suggesting a role for intrauterine dexamethasone in reversing fetal myocarditis and slowing conduction disease.

C. **Antiphospholipid antibody syndrome** is characterized by the presence of antiphospholipid antibodies or lupus anticoagulant, recurrent venous or arterial thrombosis, and miscarriages. APLAs can occur independently, referred to as primary APLAs, or can be associated with other autoimmune diseases such as SLE (10% to 30%) and are then referred to as secondary APLAs. Valvular disease is common in APLAs and is characterized by noninfectious vegetations similar to those seen in SLE (Libman-Sacks endocarditis). Management of arterial or venous thrombosis or significant valvular vegetations includes anticoagulation therapy with warfarin. Monitoring anticoagulant effect while on heparin or warfarin may be difficult, as these patients can have prolonged partial thromboplastin time or international normalized ratio at baseline, in which case monitoring of anticoagulant effect can be done using activity levels of factors II and X.

D. **Scleroderma** or systemic sclerosis is a rare autoimmune disorder, characterized by vasospasm, microvascular occlusion, and fibrosis of skin and multiple organs. Diffuse or progressive systemic sclerosis (PSS) results in widespread cutaneous and visceral involvement. Limited scleroderma, also known as CREST syndrome, is characterized by calcinosis cutis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia. Cardiovascular involvement can occur in progressive as well as limited scleroderma.

1. **Pericardial disease** in the form of fibrinous pericarditis is present in over 70% of patients on autopsy studies, though it is clinically manifest as symptomatic pericarditis in only about 15% to 30% of patients. Small pericardial effusions can be detected in about 40% of patients by echocardiography, but are rarely significant. Acute pericarditis may be treated with NSAIDs, with close monitoring of renal function. Corticosteroids carry the risk of inducing scleroderma renal crisis.
2. **Pulmonary hypertension (PH)** is responsible for significant morbidity and mortality in patients with scleroderma and is more common in the limited type. Autopsy studies have shown histopathological changes consistent with PH in 65% to 80% of patients with scleroderma; however, < 10% of patients manifest PH clinically. Patients with scleroderma and PH appear to have a worse prognosis compared with those with primary PH, with a 2-year survival of < 50%. Drugs for PH, such as prostacyclins (epoprostenol, treprostinil, and iloprost), endothelin receptor antagonists (bosentan and ambrisentan), and phosphodiesterase inhibitors (sildenafil and tadalafil), have been studied in patients with scleroderma and PH. Some of these studies have demonstrated improvement in the 6-minute walk test, exercise capacity, and cardiopulmonary hemodynamics; however, no improvement in mortality has been demonstrated. Echocardiography should be used to screen for asymptomatic PH.
3. **Scleroderma renal crisis** is defined as the new onset of accelerated hypertension or rapidly progressive oliguric renal failure during the course of systemic sclerosis. It is usually associated with rising creatinine, thrombocytopenia, microangiopathy, and signs and symptoms of congestive heart failure. Scleroderma renal crisis occurs in about 10% of patients with scleroderma and is more common in the diffuse form of the disease. Angiotensin-converting enzyme inhibitors are the mainstay of therapy.
4. **Myocardial involvement** with patchy fibrosis can occur in patients with scleroderma. Epicardial coronary arteries are usually normal on angiography; however, ischemia can occur secondary to microvascular vasospasm. Diastolic dysfunction has been commonly found in these patients. Electrical abnormalities such as frequent ectopy, supraventricular arrhythmias, and nonsustained ventricular tachycardia (VT) can occur in patients with PSS. The risk of sudden cardiac death is higher in those with a history of syncope.

E. **Seronegative spondyloarthropathies** include HLA-B27 antigen–associated arthropathies such as ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and inflammatory bowel disease–associated arthritis. These disorders are characterized by

involvement of the spine and sacroiliac joints and inflammation of tendons, ligaments, and their insertion points into bones (enthesitis). In contrast to RA and SLE, these disorders occur more commonly in males. Ankylosing spondylitis results in ankylosis, sacroiliitis, and asymmetric peripheral arthritis. Reactive arthritis is characterized by conjunctivitis, genital ulcers, and asymmetric peripheral arthritis. Proximal aortitis with or without aortic regurgitation and conduction disturbances are most commonly associated with ankylosing spondylitis and reactive arthritis. **Proximal aortitis can lead to thickening, stiffness, and dilatation of the aortic root with aortic regurgitation**. Aortic or mitral valve thickening with nodularities of the aortic cusps and thickening of the anterior mitral valve leaflet resulting in a characteristic subaortic bump are commonly observed valvular abnormalities in patients with ankylosing spondylitis. Extension of the subaortic inflammation and fibrotic process into the basal septum can result in conduction abnormalities such as heart block, which is usually at the level of the atrioventricular (AV) node. Other less common cardiac abnormalities include pericarditis, diastolic dysfunction, and supraventricular arrhythmias.

F. Dermatomyositis (DM) and polymyositis (PM) are idiopathic inflammatory myopathies characterized by proximal skeletal muscle weakness and elevated levels of muscle enzymes, such as creatine kinase and aldolase. DM is characterized, in addition, by skin involvement such as erythematous scales on the knuckles (Gottron's papules), knees, and elbows, and periorbital swelling and violaceous rash around the eyelids (heliotrope rash). DM can be part of a paraneoplastic syndrome, particularly in the elderly. Cardiovascular manifestations of DM and PM include pericarditis, conduction abnormalities, and congestive heart failure secondary to myocarditis that can be focal or generalized and may be steroid responsive. Cardiac magnetic resonance imaging (MRI) with delayed gadolinium enhancement may be useful in monitoring response to therapy. Coronary vasculitis is a rare manifestation. The differentials for muscle weakness include the following: corticosteroid myopathy, which generally affects skeletal muscle but not cardiac or respiratory muscle and is associated with a normal creatine kinase, and statin myopathy, which can be differentiated based on history of statin use and myalgias or with electromyography and biopsy if needed. Management of DM and PM includes corticosteroids, and adjunctive therapies include methotrexate, azathioprine, and intravenous immunoglobulin (IVIg).

II. SYSTEMIC VASCULITIDES

A. Giant cell arteritis (GCA), also referred to as temporal arteritis, is the most common vasculitis in patients older than 50 years. It is more prevalent in women compared with men and in those of Northern European descent. GCA usually affects the extracranial branches of the aorta, sparing the intracranial vessels. Transmural inflammation of the vessels is followed by intimal hyperplasia, luminal occlusion, and end-organ ischemia. Branches of the external and internal carotid arteries are particularly susceptible, and the typical clinical presentation of GCA includes new-onset headache, scalp and temporal artery tenderness, jaw pain, acute visual loss, and polymyalgia rheumatica. Concomitant elevation in erythrocyte sedimentation rate (ESR) is almost always present. **Temporal artery biopsy is the gold standard for diagnosis and shows transmural chronic granulomatous inflammation with destruction of elastic laminae**. Treatment with corticosteroids should be initiated as soon as possible, without waiting for temporal artery biopsy. GCA is associated with thoracic and abdominal aortic aneurysms. According to one study, patients with GCA are 17 times more likely to develop thoracic aortic aneurysm and 2.4 times more likely to develop abdominal aortic aneurysm compared with age-matched controls. Rare cardiovascular manifestations include pericarditis, myocarditis, and coronary vasculitis. Studies have shown that MRI or fluorine-18-deoxyglucose positron emission tomography (FDG PET) can be useful for the detection of large vessel vasculitis. Transthoracic echocardiography and abdominal ultrasonography are useful in screening for thoracic and

FIGURE 39.2 Magnetic resonance angiogram in a patient with Takayasu arteritis demonstrating severe diffuse narrowing of both common carotid arteries and severe disease in the left subclavian artery (arrows).

abdominal aortic aneurysms. As mentioned, corticosteroids are the agents of choice in patients with GCA. Low-dose aspirin should be added, since it has been shown to reduce the rate of blindness and stroke in patients with GCA.

B. Takayasu arteritis (TA) is also a large vessel vasculitis like GCA, but it occurs in young women, particularly of Indian, Japanese, and African-American descent. It typically affects the aorta and its major branches (Fig. 39.2). In TA, arterial stenoses are more common than aneurysms. Clinically, TA is characterized by claudication (upper extremities more common compared with lower extremities), "pulselessness" or asymmetric pulses, and blood pressures. Systemic symptoms such as fever, malaise, arthralgias, myalgias, night sweats, and elevated ESR may indicate active disease. Renal artery stenosis can be associated with hypertension. Cardiac manifestations include aortic regurgitation secondary to aortic root dilatation and rarely coronary arteritis. Diagnosis is based on imaging studies that show vascular involvement typical of TA. Imaging modalities such as MRI and PET enable visualization of inflammation in the vessel wall. Therapeutic strategies include corticosteroids, immunosuppressants such as cyclophosphamide or methotrexate in steroid-resistant cases, and anatomic correction using an endovascular or surgical approach when feasible.

C. Kawasaki disease is an acute febrile illness that affects children, usually below the age of 5 years, with the highest incidence in those of Asian descent. Diagnosis is made largely on clinical grounds based on the following criteria: (1) fever ≥5 days; (2) conjunctival injection; (3) oropharyngeal changes including erythema, swelling and fissuring of the lips, diffuse erythema of the oropharynx or strawberry tongue; (4) extremity changes such as erythema of palms and soles, induration of hands and feet, desquamation of the skin of hands and feet; (5) polymorphous rash; and (6) cervical lymphadenopathy, usually a single node > 1.5 cm. Fever and four out of five remaining criteria must be present for a definitive diagnosis. Cardiovascular manifestations include pericarditis, myocarditis, aortitis, aortic regurgitation, and arrhythmias. Coronary vasculitis can occur, which if left untreated can lead to

coronary aneurysm formation in about 4 weeks. Aneurysms larger than 8 mm are referred to as giant aneurysms, and these can thrombose acutely, leading to myocardial infarction as well as sudden death. Treatment with aspirin and single-dose IVIg (dose 2 g/kg) reduces the formation and progression of coronary aneurysms. Recommendations by the American Heart Association include long-term follow-up and consideration of anticoagulation for children with multiple giant coronary aneurysms or known obstructive lesions, chronic low-dose aspirin therapy, and coronary artery bypass or percutaneous intervention if lesions are severe and symptomatic.

D. Idiopathic aortitis is commonly associated with disorders such as TA and GCA in addition to rheumatologic diseases such as SLE, Behçet's disease, seronegative spondyloarthropathies, antineutrophil cytoplasmic antibody–associated vasculitides, Cogan syndrome, and sarcoidosis. Although most cases of aortitis are noninfectious in etiology, infectious causative agents such as staphylococcus, streptococcus, salmonella, and syphilis must be considered. Aortitis can be diagnosed for the first time in surgically excised specimens after aortic surgery. In a 20-year review of over 1,200 aortic surgical specimens at Cleveland Clinic, 52 (4.3%) were clinically and pathologically classified as idiopathic aortitis. Of these, 67% were women. In 96% of cases with idiopathic aortitis and aneurysm formation, aortitis was limited to the thoracic aorta. In 96% of cases, signs of systemic illness were not present at the time of aortic surgery. In 31% (16 of 52), aortitis was associated with a remote history of vasculitis and a variety of other systemic disorders such as GCA, TA, SLE, and Wegener's. Over a mean follow-up of 41 months, new aneurysms were found in 6 out of 25 patients not treated with corticosteroids. It is prudent to follow these patients with serial imaging to identify new aneurysms. Treatment with corticosteroids requires evidence of an ongoing systemic inflammatory disease.

E. Churg-Strauss syndrome (CSS) is a rare small vessel vasculitis characterized by asthma, peripheral eosinophilia, pulmonary infiltrates, and varying degrees of cutaneous, renal, neurologic, and cardiac involvement. Histopathologically, it is characterized by eosinophilic granulomatous inflammation of small vessels of the involved organ. Cardiovascular manifestations are common in CSS and are responsible for significant morbidity and mortality in these patients. The most common cause of death is congestive heart failure secondary to cardiomyopathy, the cause of which may be small vessel vasculitis or eosinophilic infiltration of the myocardium followed by fibrosis or a combination of both pathologic processes. Other cardiac manifestations include myocarditis and pericarditis with or without pericardial effusion. Therapy mainly includes corticosteroids but other immunosuppressants may be needed.

F. Polyarteritis nodosa (PAN) is a rare nongranulomatous disease affecting medium-sized arteries that leads to weakening of the vessel wall secondary to necrotizing changes with aneurysm formation or intimal proliferation and stenosis. It is a systemic disease characterized by painful subcutaneous nodules, digital infarcts, mononeuritis multiplex, renal infarction and renal failure, hypertension, and pulmonary infarction. Cardiac manifestations include angina, myocardial infarction, congestive heart failure, and arrhythmias such as supraventricular tachycardia. Treatment is similar to CSS and primarily includes corticosteroids.

III. CONNECTIVE TISSUE DISEASES

A. Marfan syndrome was first described over 100 years ago by Antoine-Bernard Marfan, a French pediatrician. It is an autosomal dominant connective tissue disease secondary to mutations in the fibrillin-1 gene (*FBN1*) that encodes major constituent proteins of microfibrils, which form a significant component of the extracellular matrix. It is a common heritable condition with an estimated prevalence of 1 per 3,000 to 5,000 individuals. About 25% cases have no family history and are a result of de novo mutations. Marfan syndrome is characterized by disproportionate long bone overgrowth with long extremities and tall stature, joint hypermobility,

high-arched palate, and ectopia lentis. In addition, patients with Marfan syndrome can have pectus excavatum or carinatum, scoliosis, arachnodactyly, erosion of lumbar vertebrae from dural ectasia, apical pulmonary blebs with spontaneous pneumothorax, myopia, retinal degeneration, and cataracts. The diagnosis of Marfan syndrome is based on the Ghent criteria, based on consensus by an international expert panel, which have been revised recently with more weight on cardiovascular manifestations. In the absence of family history, the presence of aortic root aneurysm or aortic dissection and ectopia lentis establishes the diagnosis of Marfan syndrome. In the absence of either of these two, the presence of *FBN1* gene mutation or a combination of systemic manifestations listed above is required. Cardiovascular manifestations of the Marfan syndrome are as follows:

1. **Aortic aneurysm and dissection.** Defect in microfibrils results in degeneration of elastic fibers in the aortic media (sometimes inappropriately referred as "cystic medial necrosis"), with resultant aortic aneurysm formation. This typically occurs at the level of the aortic root and involves the sinuses of Valsalva. The aortic root diameter should be serially monitored with echocardiography or computed tomography/MRI. According to the current guidelines, annual imaging is recommended if stability in aortic root size is documented. If the baseline aortic diameter is > 4.5 cm or if there is significant growth from baseline, more frequent imaging should be considered. Elective surgical repair for aortic root aneurysm is usually performed at a threshold of 5 cm or greater in patients with Marfan syndrome. This threshold is smaller than for other disorders with aortic aneurysm, given the greater tendency for aortic dissection at smaller diameters in patients with Marfan syndrome. Indications for earlier repair at sizes < 5.0 cm include: rapid growth defined as > 0.5 cm/year, family history of aortic dissection at a diameter < 5.0 cm or the presence of significant aortic regurgitation. Aortic regurgitation usually occurs secondary to aortic root dilatation. Aortic dissection in Marfan syndrome is usually type A, i.e., starts in the ascending aorta and can extend to a variable degree distally. About 10% of dissections in Marfan syndrome begin distal to the origin of the left subclavian artery (type B). Type A dissection necessitates immediate repair, given the high risk of life-threatening complications if not treated promptly. Medical management in patients with Marfan syndrome includes β-blockers, which have been shown to reduce the risk of aortic dilatation and aortic dissection. The beneficial effect of β-blockers is largely due to the reduction in heart rate and the rate of pressure increase in the aorta, which leads to less stress on the aortic wall. Recently, angiotensin receptor blockade with Losartan was shown to slow the rate of aortic root dilatation in patients with Marfan syndrome, secondary to mitigation of excessive transforming growth factor beta signaling. Due to the risk of acute aortic dissection, patients with Marfan syndrome should be counseled to avoid isometric exercise, including heavy weight lifting, contact sports, and competitive athletics. Females of childbearing age with Marfan syndrome should be counseled regarding the high risk of transmission of their disease to the child. Enlargement of the aortic root to > 4.0 cm increases the risk of aortic dissection, particularly during the third trimester, parturition, and first few months postpartum. If the aortic root is < 4 cm, then the risk of dissection is considered low, and pregnancy can be allowed with β-blocker therapy and careful monitoring with serial echocardiography throughout pregnancy.
2. **Mitral valve prolapse** commonly occurs in patients with Marfan syndrome and is more common in women. The incidence is as high as 60% to 80%, and progressive mitral regurgitation occurs in about 25% of patients. The valve leaflets are usually thickened and redundant and occasionally ruptured chordae or prolapse may be present. Progressive untreated mitral regurgitation can lead to left ventricular dilatation, congestive heart failure, and PH. Tricuspid valve

prolapse can occur concomitantly. Standard management for chronic severe mitral regurgitation is indicated in symptomatic patients, with repair of the mitral apparatus if possible, but replacement may be necessary when the leaflets are very redundant or there is severe annular calcification or chordal damage.

3. **Dilated cardiomyopathy** independent of, or out of proportion to, valvular abnormalities can occur in patients with Marfan syndrome. This has been hypothesized to be secondary to a potential role of fibrillin mutations in the reduction of myocardial function.
4. **Arrhythmias**, both supraventricular and ventricular, can occur in patients with Marfan syndrome.

B. Loeys-Dietz syndrome (LDS) is a recently recognized autosomal dominant connective tissue disease with similarities to the Marfan syndrome but with important genotypic and phenotypic differences. It is caused by mutations in the genes encoding transforming growth factor beta receptors 1 and 2 (*TGFBR1* and *TGFB2*). Type I LDS is characterized by arterial tortuosity and aneurysms, most often in the aortic root but can involve other arteries, hypertelorism (widely spaced eyes), and bifid uvula or cleft palate or both. Patients with type II LDS are characterized by cutaneous manifestations such as velvety translucent skin, easy bruising, atrophic scars, and joint laxity, similar to vascular Ehlers-Danlos syndrome. Patients with LDS do not have ectopia lentis. They are, however, predisposed to more aggressive and widespread vascular disease, including aneurysm formation and dissection, compared with Marfan syndrome, with a mean age of death of 26 years. Patients with LDS can develop aortic dissection at aortic diameters < 5 cm; hence, elective repair is recommended at much smaller aortic root dimensions (4.0 cm) compared with Marfan syndrome. Surgical repair has not been associated with tissue fragility in patients with LDS. More than 50% of patients with LDS can develop aneurysms of other vessels; hence, yearly surveillance imaging of the entire vascular tree has been recommended.

C. Ehlers-Danlos syndrome, type IV or vascular form, is a rare autosomal dominant disorder associated with mutations in the gene for type III procollagen (*COL3A1*). It is characterized by easy bruising, thin skin with visible veins, characteristic facial features, and rupture of arteries, uterus, or intestines. Arterial rupture or dissections are the major causes of mortality in these patients and can occur in the thoracic or abdominal vessels, including aortic rupture or dissection. The median age of survival was about 48 years in a study of 220 patients with this disorder. In the same study, 25% of patients had a medical or surgical complication by the age of 25 years and > 80% had such complications by the age of 40 years. In contrast to LDS, tissues are friable in Ehlers-Danlos syndrome, and surgical repair after ruptured aneurysm or dissection can be complicated by hemorrhage or poor wound healing. The role of prophylactic surgical repair for unruptured aneurysms is unclear. Pregnant women have a 50% chance of transmitting the disorder to the child, and about 11.5% risk of mortality. Pregnancy should be considered high risk and women should be counseled against it.

IV. OTHER SYSTEMIC DISEASES

A. Sarcoidosis is an idiopathic systemic granulomatous inflammatory disease affecting mainly the lungs, but can involve the lymph nodes, skin, eyes, heart, kidneys, musculoskeletal system, nervous system, and endocrine system. Histopathologically, it is characterized by the presence of noncaseating granulomas. It is more common in young and middle-aged adults (peak incidence second to fourth decades) and in African-Americans. Cardiac involvement is found in 25% of patients with sarcoidosis on autopsy, but only 5% of patients have clinically apparent cardiac involvement. The most common sites of cardiac involvement are the basal interventricular septum, AV node and the His bundle, focal regions in the ventricular free walls, and the papillary muscles. Cardiovascular manifestations of sarcoidosis are as follows:

1. **Arrhythmias** can vary from conduction disturbances, including heart block to fatal ventricular arrhythmias. Complete heart block is the most common abnormality in

patients with clinically evident sarcoidosis and is found in 20% to 30% of patients. First-degree heart block and bundle branch blocks are also seen. Granulomatous infiltration of the ventricular myocardium can set up foci of automaticity, leading to ventricular arrhythmias. VT is the most common arrhythmia and is reported in about 20% of patients with sarcoidosis. Sudden cardiac death caused by an arrhythmia is one of the leading causes of death (> 60%) in patients with sarcoidosis.

2. **Congestive heart failure** may occur, secondary to widespread infiltration of the myocardium. It may also occur due to arrhythmias, cor pulmonale from long-standing PH, valvular abnormalities, or a combination of these abnormalities. Progressive congestive heart failure is the second most common cause of death in patients with sarcoidosis.
3. **Pericardial** involvement can manifest as pericarditis, pericardial effusion, and constrictive pericarditis.

Diagnosis of cardiac sarcoidosis may be difficult. Endomyocardial biopsy with noncaseating granulomas has high specificity, but poor sensitivity owing to the patchy nature of myocardial involvement particularly in the basal septum, whereas the location of biopsy is often the apical septum. Electrocardiogram often reveals conduction abnormalities but has poor sensitivity. Echocardiographic findings include increased ventricular septal thickness (secondary to granulomatous expansion) or wall thinning (due to fibrosis), aneurysms, regional wall motion abnormalities, and eventually ventricular dilatation. Contrast-enhanced MRI and 18-FDG PET are more sensitive modalities for detecting early cardiac involvement and findings correlate with disease severity. These imaging modalities can be used in evaluating response to therapy. Corticosteroid therapy can halt cardiac disease progression and improve survival; however, it does not prevent sudden cardiac death. Pacemaker implantation is often necessary in cases of symptomatic heart block or asymptomatic high-grade conduction disease. Implantable cardioverter defibrillator implantation is recommended for primary prevention in patients with cardiac sarcoidosis at risk for sudden cardiac death, such as those with a history of nonsustained VT or low ejection fraction. Cardiac transplantation for cardiac sarcoidosis is rarely used, as the disease can recur in the transplanted heart. However, it may be considered in young patients with severe end-stage heart failure or resistant VT.

CHAPTER 40

Arun Dahiya

Pericardial Disease

I. INTRODUCTION. The pericardium is a fibrous sac composed of two layers. The inner monocellular visceral layer is composed of mesothelial cells and is adherent to the myocardium. The outer parietal layer is a fibrous layer < 2 mm thick that consists mostly of collagen and elastin. It is joined to adjacent intrathoracic structures by means of ligaments. Interspersed between the two layers is a small amount of serous pericardial fluid, generally about 15 to 35 mL. **The normal pericardium is distensible and permits unimpeded expansion of the ventricles during diastole. Normally, changes in intrathoracic pressure are easily transmitted to the heart**, resulting in increased venous return to the right side of the heart with inspiration and increased pulmonary venous return to the left side of the heart with expiration.

The pericardium helps to maintain the position of the heart within the chest cavity, acts to reduce friction during the cardiac cycle, and also acts as a barrier to infection and inflammation. The pericardium secretes prostaglandins that can modulate cardiac reflexes and coronary tone.

A. Acute pericarditis is a clinical syndrome caused by **inflammation of the pericardium,** and it is associated with **chest pain, a friction rub, and characteristic electrocardiographic changes**. The incidence of acute pericarditis is 2% to 6% in autopsy series, although it is diagnosed clinically in only 1 in 1,000 admissions. It is more **common in adults (20 to 50 years of age) and in men**.

B. Constrictive pericarditis is caused by **fibrous thickening of the pericardium** secondary to **chronic inflammation** from a variety of causes.

C. Pericardial effusion is a **fluid collection in the pericardial space**. The clinical presentation may range from being **asymptomatic to life-threatening** hemodynamic compromise, depending on the **underlying cause of the effusion** and the **rate of accumulation**, as discussed later in detail.

D. Cardiac tamponade is a clinical emergency that arises when a pericardial fluid collection impairs diastolic filling sufficiently to produce a low cardiac output state.

II. ACUTE PERICARDITIS.

There are a large number of potential etiologies of acute pericarditis. In practice, these are classified into the following groups: idiopathic, infectious, inflammatory, uremic, post-myocardial infarction (post-MI), neoplastic, and traumatic (Table 40.1).

A. Etiology

1. Idiopathic. Most cases of acute pericarditis are **idiopathic**, although many of these may be **viral in origin**.

TABLE 40.1 Causes of Pericarditis

Idiopathic (nonspecific)

Viral infections: coxsackievirus A, coxsackievirus B, echovirus, adenovirus, mumps virus, infectious mononucleosis, varicella, hepatitis B virus, and acquired immunodeficiency syndrome

Bacterial infections: *Pneumococcus, Staphylococcus, Streptococcus,* gram-negative septicemia, *Neisseria meningitidis, Neisseria gonorrhoeae,* tularemia, *Legionella pneumophila, and Mycobacterium tuberculosis*

Fungal infections: histoplasmosis, coccidioidomycosis, *Candida,* and blastomycosis

Uremia

Neoplasm: lung cancer, breast cancer, leukemia, Hodgkin's disease, and lymphoma

Radiation

Autoimmune diseases: acute rheumatic fever, systemic lupus erythematosus, rheumatoid arthritis, scleroderma, mixed connective tissue disease, Wegener's granulomatosis, and polyarteritis nodosa

Inflammatory disease: sarcoidosis, amyloidosis, inflammatory bowel disease, Whipple's disease, and temporal arteritis

Drugs

Hydralazine, procainamide, phenytoin, isoniazid, phenylbutazone, doxorubicin, and penicillin

Trauma

Postmyocardial–pericardial injury syndromes: postmyocardial infarction syndrome (Dressler's syndrome) and postpericardiotomy syndrome

Dissecting aortic aneurysm

Adapted from Lorell BH. Pericardial disease. In: Braunwald E, ed. *Heart Disease: A Textbook of Cardiovascular Medicine.* 5th ed. Philadelphia, PA: WB Saunders; 1997:1482.

2. **Viral pericarditis.** The most commonly involved viruses are coxsackievirus B and echovirus. A **prodrome of upper respiratory tract symptoms** preceding the onset of chest pain, along **with a fourfold or higher rise in viral convalescent antibody titers**, supports the diagnosis. Most cases are self-limited; infrequent complications include myocarditis (i.e., myopericarditis), recurrent pericarditis, pericardial effusion, tamponade, and constrictive pericarditis.
3. **Purulent pericarditis.** Purulent pericarditis usually occurs as a **complication of pneumonia or empyema** caused by staphylococci, pneumococci, or other streptococci. Early diagnosis of purulent pericarditis is paramount, as **cardiac tamponade often develops and is associated with high mortality. Purulent pericarditis** is characterized by **acute onset of fever, shaking chills, night sweats, and dyspnea** of a few days duration. **Chest pain or pericardial friction rub is not necessarily present**.
4. **Tuberculous pericarditis.** Although uncommon in the United States, this entity should be considered in patients with fever and pericardial effusion, particularly if there is an underlying immunocompromised state. Pericardial involvement occurs in 1% to 2% of cases of pulmonary tuberculosis. **If the clinical suspicion is high, the patient should be hospitalized and started on triple drug therapy**, while definitive diagnostic testing is undertaken (acid-fast bacilli [AFB] testing and pericardial/pleural biopsy).
5. Post-MI pericarditis occurs most often after a large anterior wall MI. Because post-MI pericarditis is a marker for extensive myocardial necrosis, these **patients are at an increased risk for congestive heart failure and mortality at 1 year after MI**. It is notable that the rate of post-MI pericarditis has declined since the introduction of successful reperfusion therapies.
6. **Dressler's syndrome** usually **occurs weeks to several months after MI,** with an incidence of about 1%. It presents as **malaise, fatigue, and chest pain** that can be of concern for recurrent MI. The cause of Dressler's syndrome is unclear, although it has been proposed to be autoimmune in nature.
7. **Postpericardiotomy syndrome.** Although similar to Dressler's syndrome in presentation, it **usually occurs within the first 6 to 8 weeks following cardiac surgery**. The incidence varies from 10% to 40%, and the syndrome is believed to be caused by an autoimmune reaction.
8. Uremic pericarditis typically develops in patients who are just beginning renal replacement therapy with hemodialysis. The majority present with a **rub**, and the associated **pericardial effusions tend to be large**. The cause is unknown but does not seem to be related to the level of circulating uremic catabolites or toxins.
9. **Neoplastic pericarditis.** Tumors involving the pericardium are typically metastatic in nature (lung, breast, Hodgkin's and non-Hodgkin's lymphoma, and leukemia). It is important to **suspect cardiac tamponade in patients with a known malignancy who present with symptoms of relatively acute onset fatigue, dyspnea, or edema**.
10. **Autoimmune and inflammatory.** Lupus, rheumatoid arthritis, vasculitis, and other rheumatologic disorders are also associated with pericarditis.

B. Clinical presentation

1. **Signs and symptoms**
   - **a.** Chest pain from pericarditis is described as a severe, sharp retrosternal pain that may radiate to the neck, shoulders, and back, worsening when lying supine, coughing, or during inspiration. The pain may be alleviated when the patient leans forward.
   - **b.** There may be a **prodrome of fever and myalgias**.
   - **c.** Dyspnea may result from shallow breathing due to inspiratory chest pain.
   - **d.** Patients with **purulent pericarditis** may appear toxic with **high fevers, shaking chills, and night sweats**.

e. Tuberculous pericarditis is characterized by gradual onset of symptoms with chronic, nonspecific, constitutional symptoms such as **fever, chills, and night sweats**.

2. **Physical findings**
   a. The **pericardial friction rub is the major clinical finding in pericarditis,** but it is not present in all cases. It is described as a **scratchy, grating, and high-pitched sound**. The rub is often evanescent, changes in quality and intensity on serial examinations, and may be accentuated with deep respiration. Classically, it has **three components**, corresponding to atrial systole, ventricular systole, and early ventricular diastole. Most often, however, it is a **biphasic** rub consisting of the atrial and ventricular systolic components.
   b. **Auscultation of the rub is ideally performed** using the diaphragm of the stethoscope **at the left lower sternal border** during inspiration, with the patient leaning forward.

C. **Laboratory examination and diagnostic testing.** Pericarditis is a **clinical diagnosis based on history, physical examination, chest radiograph, and serial electrocardiographic changes**. Based on the clinical scenario, some patients may require further testing, such as tuberculin skin testing, fungal tests, viral serologies, cold agglutinins, thyroid function tests, heterophile antibodies, antinuclear antibodies, rheumatoid factor, bacterial culture, and cytology.

1. **Electrocardiography.** The associated electrocardiographic changes evolve through **four stages** (Table 40.2). Although these changes occur in most patients, their **absence does not exclude acute pericarditis**, particularly in patients with neoplastic or tuberculous pericarditis.
   a. The first stage usually occurs within hours of the onset of chest pain and is diagnostic of acute pericarditis (Fig. 40.1). The presence of **stage 1 electrocardiographic changes is most useful in confirming the diagnosis of acute pericarditis,** yet such changes are often **difficult to distinguish from changes associated with early repolarization and acute infarction**. There is **diffuse ST-segment elevation with upright T waves** in all leads

TABLE 40.2 Typical Electrocardiographic Evolution of Acute Pericarditis

Stage	J-ST	T waves	PR segment
"Epicardial" leads (I, II, aVL, aVF, and V_3–V_6)			
I	Elevated	Upright	Depressed or isoelectric
II (early)	Isoelectric	Upright	Isoelectric or depressed
II (late)	Isoelectric	Low to flat to inverted	Isoelectric or depressed
III	Isoelectric	Inverted	Isoelectric
IV	Isoelectric	Upright	Isoelectric
"Endocardial" leads (aVR, often V1, and sometimes V2)			
I	Depressed	Inverted	Elevated or isoelectric
II (early)	Isoelectric	Inverted	Isoelectric or elevated
II (late)	Isoelectric	Shallow to flat to upright	Isoelectric to elevated
III	Isoelectric	Upright	Isoelectric
IV	Isoelectric	Inverted	Isoelectric

Modified from Spodick DH. Electrocardiographic changes in acute pericarditis. *Am J Cardiol*. 1974;33:470.

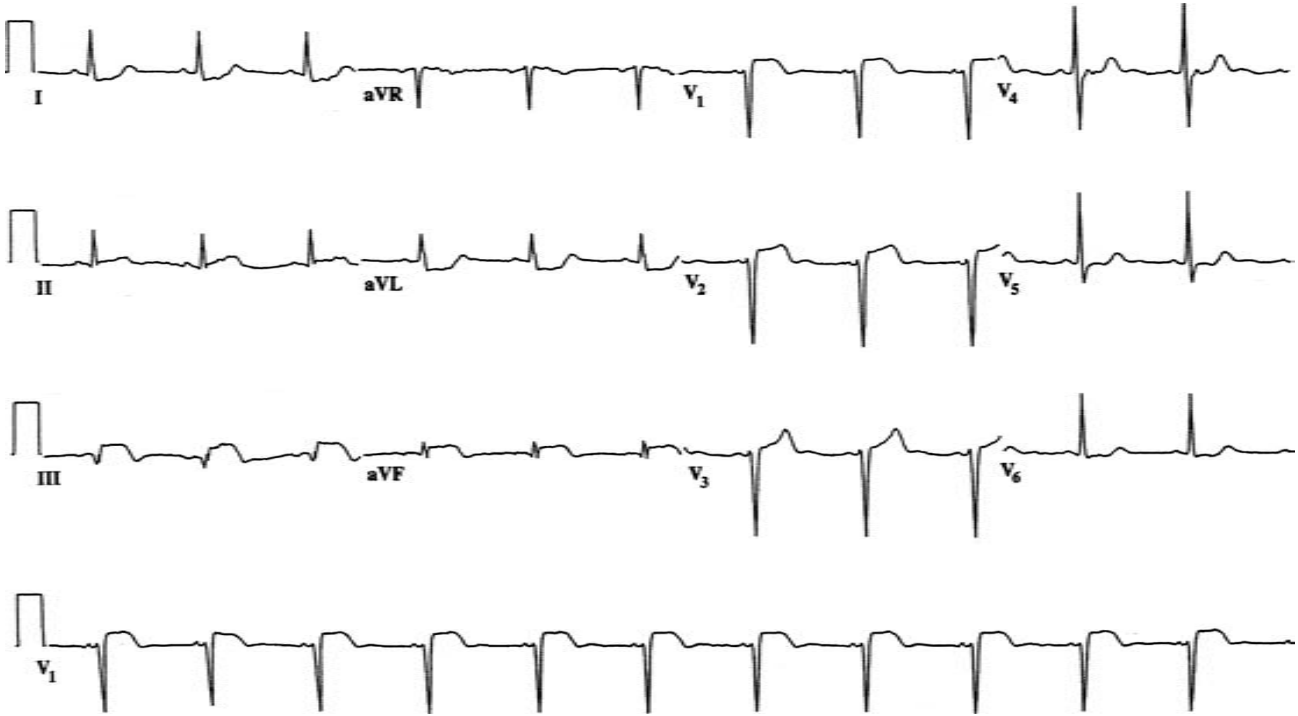

FIGURE 40.1 Stage 1 electrocardiographic changes in acute pericarditis. Note PR segment elevation in lead aVR, and diffuse ST elevation and the upsloping nature of ST segments as compared with acute myocardial infarction.

except aVR and V_1. **PR-segment depression** is seen in all leads except aVR and V_1. There is often PR-segment elevation in lead aVR (the "knuckle" sign).

b. Stage 2, which occurs several days later, is characterized by resolution of PR/ST segments to baseline and T-wave flattening.

c. The T-wave inversions mark **stage 3**.

d. Stage 4 occurs when T waves become upright again, which may take days to weeks.

e. With a large **effusion,** the electrocardiogram (ECG) may show **electrical alternans or low voltage**.

2. A chest radiograph may reveal **cardiomegaly** and may yield important information in support of tuberculous or neoplastic processes.

3. Blood cultures along with sputum and gastric aspirate for tuberculosis should be done where such a diagnosis of purulent or tuberculous pericarditis is suspected (including in immunosuppressed immigrants). Pericardial or pleural biopsy may be necessary to diagnose tuberculosis.

4. Blood tests may reveal leukocytosis or an elevated erythrocyte sedimentation rate, which are nonspecific markers of inflammation. Mild **elevations in the** creatine kinase myocardial band **(CK-MB) fraction or cardiac troponin levels can be seen** and suggest a more extensive acute inflammatory process involving the epicardium; significant elevations in these markers should raise suspicion for more extensive myocardial involvement, referred to as **myopericarditis**.

5. Echocardiography

a. Pericarditis is not an echocardiographic diagnosis and a normal echocardiogram does not preclude pericarditis. Echocardiography should be performed when **symptoms last longer than a week, to evaluate for hemodynamic abnormalities**.

b. If the patient has had **recent cardiac surgery,** is **elderly,** or if there is a **suspicion for pericardial effusion, echocardiography** should be done as **part of the initial workup**.

6. Computed tomography (CT), magnetic resonance imaging (MRI), or transesophageal echocardiography (TEE) can be done in select cases for further investigation of the pericardium (refer to Chapters 52, 51, and 68, respectively, for detailed discussions on these modalities).

D. Differential diagnosis

1. Chest pain from acute pericarditis can mimic **aortic dissection, pulmonary embolism, pneumothorax, or acute coronary syndrome**.

2. Electrocardiographic changes can also mimic **myocardial ischemia**; however, the ST segments of pericarditis are usually concave upward with upright T waves. Echocardiography may assist in distinguishing between pericarditis and ischemia by assessing for segmental wall motion abnormalities, which are usually absent in pericarditis.

E. Therapy. Most cases of acute pericarditis are **uncomplicated and self-limited and such patients can be managed in the outpatient setting. However, inpatient management should be considered in patients with large pericardial effusion or coexisting myocarditis**. These typically respond to conservative medical therapy. First-line therapy usually consists of **nonsteroidal anti-inflammatory drugs** (NSAIDs) **with the addition of colchicine in some cases**.

1. Medical therapy

a. Ibuprofen has a good safety profile and is a reasonable first-line therapy at doses of 600 to 800 mg orally three times a day for at least 2 weeks. A**spirin** 650 mg orally every 6 to 8 hours for 2 to 4 weeks is an alternative therapy. Other NSAID agents, including naproxen, seem to be similarly efficacious.

b. If the **patient does not respond to NSAIDs**, or in cases of recurrent pericarditis, **colchicine** should be considered in addition to NSAIDs. A randomized controlled trial, colchicine for acute pericarditis (COPE), of 120 patients

with a first episode of acute pericarditis demonstrated superior efficacy of a combined regimen of aspirin with colchicine. The usual dosing of colchicine is 1 to 2 mg for the first day and then 0.5 to 1 mg daily for 3 months.

c. **Prednisone** should be used only in patients with recurrent pericarditis with persistent symptoms despite NSAIDs and colchicine therapy or in cases where there is an underlying inflammatory disease that is responsive to corticosteroid therapy. Prednisone should be dosed at 1 to 1.5 mg/kg for at least 1 month and should be tapered slowly. In the COPE trial, **corticosteroid therapy was an independent risk factor for recurrence**.

d. **Post-MI pericarditis patients should *not* be treated with prednisone**, given the risk of myocardial rupture. Treatment with aspirin is recommended (650 mg every 6 hours).

e. In cases of suspected **purulent pericarditis, empiric antibiotic therapy directed against staphylococci and streptococci** should be instituted while cultures are pending.

f. For **tuberculous pericarditis**, standard triple drug therapy is recommended for at least 9 months, with 6 months of treatment following culture conversion.

g. Pericarditis due to Dressler's syndrome should be managed with NSAIDs or aspirin. If the condition is recurrent, a trial of prednisone may be warranted.

h. Intensive dialysis is the treatment of choice for symptomatic uremic pericarditis. **Dialysis is not necessary for patients who are asymptomatic** with relatively small pericardial effusions.

2. **Percutaneous therapy**

a. Because most cases of pericarditis are self-limited, there is no role for routine pericardiocentesis, intrapericardial administration of steroids, or pericardial biopsy.

b. In cases complicated by tamponade or suspected purulent effusion or neoplasm, pericardiocentesis should be performed. Pericardiocentesis should be reserved for large, hemodynamically compromising pericardial effusions or when fluid is needed for diagnostic purposes.

c. If the etiology is uncertain, **pericardial fluid should be sent for a hematocrit and a white blood cell count with differential, glucose, protein, cytologic, and microbiologic analyses (e.g., culture for various organisms and AFB staining)**. If there is a clinical suspicion of purulent pericarditis, pericardiocentesis should be performed promptly and the fluid sent for culture. If the pericardial fluid is **serosanguineous or grossly bloody**, the clinician should send it for cytologic examination, culture, and AFB staining.

3. **Surgical therapy**

a. Subxiphoid pericardiostomy is usually performed for neoplastic pericarditis with rapidly recurrent pericardial effusions. Sclerotherapy with tetracycline has been performed in severe cases of neoplastic pericarditis; however, the procedure is painful and is associated with arrhythmias and risk for constrictive pericarditis.

b. Pericardiectomy is reserved for severe recurrent pericarditis. More commonly it is employed in the management of constrictive pericarditis, as discussed later in this chapter.

F. Follow-up

1. Most patients with idiopathic or viral pericarditis **should receive 1-month follow-up** to ensure that their symptoms have resolved and that no evidence of constrictive pericarditis exists.

2. Patients with pericardial effusions should have serial echocardiograms to assess for recurrence or an increase in the size of the effusion.

G. Prevention of postpericardiotomy syndrome (PPS). In a recent multicenter, double-blind, randomized trial, colchicine was found to be useful in preventing PPS and its related complication; however, this approach has not been widely used because of the relatively low incidence of clinically significant PPS.

H. Complications

1. **Recurrent pericarditis** can occur after an episode of acute idiopathic pericarditis, open heart surgery, cardiac trauma, or Dressler's syndrome. Natural history studies suggest that **recurrent pericarditis occurs in 20% to 30% of patients**. Recurrent pericarditis may be very bothersome. However, with appropriate management of exacerbations and prophylaxis, it frequently responds favorably and eventually peters out.
   a. Clinical presentation is similar to that of acute pericarditis, with **variable onset** from months to years after the initial episode.
   b. **Therapy.** NSAIDs and colchicine should be administered. **Only if patients fail to respond should prednisone be administered** (1 to 1.5 mg/kg) for at least 1 month and tapered slowly. Intravenous methylprednisolone can be given depending on the severity of symptoms. Most patients respond within a few days but may have recurrence with cessation of steroids. **Surgical pericardiectomy is reserved for patients with persistent recurrent pericarditis accompanied by severe chest pain despite aggressive medical therapy. It too may fail, as it is difficult to remove all of the pericardium surgically**.
   c. **Prevention.** The COPE trial has shown that **colchicine is safe and effective in the prevention of recurrent pericarditis**.
2. Cardiac tamponade will occur in about 15% of patients, most commonly after a cardiac surgical intervention or with neoplasm.
3. **Constrictive pericarditis.** Approximately 9% of patients develop mild constrictive physiology. However, this usually resolves after 3 months. Some patients develop a subacute picture of **effusive–constrictive disease**, with both effusion and pericardial thickening. This may progress to symptomatic pericardial constriction. When it does so, the interval of onset of severe constrictive findings is much more rapid than in constriction without effusive changes.

III. CONSTRICTIVE PERICARDITIS results from **a fibrous thickening of the pericardium** secondary to chronic inflammation from a variety of injuries. Essentially, the **heart is encased by the rigid pericardium**, leading to a decrease in diastolic filling, an increase in intracardiac pressures, and a **dissociation of intracardiac pressure from intrathoracic pressure. The hallmark of pericardial constriction is the equalization of end-diastolic pressures in all four cardiac chambers**. The elevated cardiac pressures and diminished diastolic filling lead to increased venous pressure, both pulmonary and systemic, and thus to progressive **signs and symptoms of right and left heart failure**. Although constrictive pericarditis is a relatively uncommon cause of heart failure, recognition of this entity is important, as its **prevalence appears to be increasing and the diagnosis is often missed.**

A. Causes of constrictive pericarditis. The **factors involved in the development of constrictive pericarditis are varied** and are similar to those of acute pericarditis (Table 40.3). However, there is **a common pathophysiologic pathway** leading to **chronic inflammation and pericardial fibrosis**. Neoplastic disease is an exception because tumor infiltration of the pericardium is often responsible for constriction. The causes of constrictive pericarditis in the decreasing order of frequency are idiopathic factors, radiation therapy, postsurgical therapy, and infectious disease. This represents a significant change from a century ago when infectious disease, specifically tuberculosis, predominated.

1. Since the advent of effective antitubercular medications, the **number of cases attributable to tuberculosis has dropped precipitously in the United States**. However, tuberculosis remains the primary cause of constrictive pericarditis in most developing regions of the world.
2. Similarly, **bacterial infections of the chest** continue to represent a large number of cases on a global scale, but these **have largely disappeared in the United States** following the introduction of antibiotics and improved drainage procedures.
3. Most **"idiopathic"** cases are **likely infectious in nature**, due to viral infections caused by viruses such as **coxsackievirus and echovirus**; however, a clear etiologic

TABLE 40.3 Common Causes of Constrictive Pericarditis

Mesothelioma
Melanoma
End-stage renal disease

link is rarely established. Less common infectious agents include fungal and parasitic organisms.

4. Constrictive pericarditis is a **late complication of radiation therapy,** generally occurring **many years after the administration of radiation**. Risk factors for development of constrictive pericarditis include duration of therapy, total amount of radiation administered, and volume of the heart in the radiation field. In contrast to other causes of constrictive pericarditis, where the myocardium is typically normal in structure and function, there may be **associated radiation damage to the myocardium**.
5. Constrictive pericarditis is a well-documented **late complication of cardiac surgery, including** coronary artery bypass grafting and valvular surgery. **Risk factors** for development of postoperative constrictive pericarditis include **intraoperative hemorrhage into the pericardium, postoperative pericarditis,** and the occurrence of **postpericardiotomy syndrome**.
6. End-stage renal disease, neoplastic disease (primarily breast, lung, and lymphoma), and connective tissue disease are less common causes that must be considered in the initial differential.

B. Pathophysiology. In constrictive pericarditis, there is **thickening and fibrosis of the pericardium with associated perimyocardial tethering,** often with superimposed calcification, resulting in **decreased ventricular compliance** (ventricular compliance = end-diastolic volume/end-diastolic pressure). However, in a small percentage of patients with constrictive pericarditis, the pericardium may not appear thickened on noninvasive imaging.

As the pericardium thickens and limits ventricular compliance, there is an **increased end-diastolic pressure for any given end-diastolic volume**. This increase in pressure **affects both ventricles equally** and effectively decreases diastolic filling and thus end-diastolic volume of both ventricles. The increased pressure is transmitted backward and results in elevated pulmonary venous and systemic venous pressures. **Equalization of end-diastolic pressures in all four cardiac chambers then ensues and is an important characteristic of constrictive pericarditis**.

1. The myocardium is generally normal in structure and function; therefore, **systole is unimpaired**.
2. Diastolic function, on the other hand, **is markedly altered** by the constrictive process. In early diastole, the ventricles expand normally, and there is rapid filling secondary to the elevated pulmonary and systemic pressures. Once the **ventricles reach the confines of the rigid pericardium,** there is an **immediate increase in ventricular pressure** and **diastolic filling comes to an abrupt halt**.
3. The result is that **nearly all ventricular filling occurs in the second phase of diastole (early filling)** with little contribution from the third phase (diastasis) and the fourth phase (atrial systole).

C. Physical signs and symptoms

1. The **early symptoms** of constrictive pericarditis are often insidious, and the patient may have nonspecific complaints such as **malaise, fatigue, and decreased exercise tolerance**.
2. As the disease progresses, **symptoms consistent with systemic congestion and low cardiac output**, such as **marked jugular venous distention, ascites, peripheral edema, and worsening exercise tolerance**, may predominate. Symptoms due to right-sided failure usually predominate over left-sided failure due to equalization of pressures.
3. **Examination of jugular veins.** Nearly all patients have **jugular venous distention**, which simply reflects the elevated right-sided pressures. Many patients demonstrate a lack of inspiratory fall in venous distention, known as **Kussmaul's sign**. This finding is sensitive but lacks specificity, as other conditions such as right ventricular (RV) hypertrophy and RV infarction also produce this sign. Observation of the jugular venous pulsations reveals a **prominent *y* descent that is produced by the rapid ventricular filling in early diastole**. The jugular venous pressure is sometimes so high in constrictive physiology that the level is not evident in the neck on examination with the patient at a 45° angle, and the diagnosis is, therefore, missed. **Appreciation of the height of the pressure may only be evident on examining the patient upright**.
4. **Cardiac examination.** Cardiac auscultation may reveal **muffled heart sounds** due to decreased transmission through the thickened pericardium. Because the mitral and tricuspid valves are nearly closed by the end of diastole, there may be a **soft first heart sound (S_1). Occasionally, one may hear a pericardial knock** in early diastole (60 to 120 milliseconds after the second heart sound [S_2]). This represents the abrupt cessation of diastolic filling that occurs when further ventricular relaxation is impeded by the rigid pericardium. The pericardial knock **must be differentiated from other early diastolic sounds** such as an opening snap, third heart sound (S_3), and tumor plop. In general, the **pericardial knock is of a higher frequency, is heard best with the stethoscope diaphragm, and occurs slightly earlier than an S_3**. An opening snap may be similar in frequency and timing but is nearly always followed by a diastolic rumble.
5. **Pulmonary examination.** Auscultation of the lung fields may reveal **decreased breath sounds at the bases**, attributed to pleural effusions.
6. **Abdominal examination.** The abdominal examination may reveal evidence of right-sided heart failure, with **hepatomegaly and splenomegaly** being frequently noted. In **severe cases, there may be** liver dysfunction and **ascites**.

7. **Examination of the extremities.** Elevated central venous pressures due to RV impairment and sodium retention due to left ventricular (LV) impairment contribute to the development of **peripheral edema**.

D. Diagnostic testing. Confirming the diagnosis of constrictive pericarditis often presents a challenge, since no gold standard test exists. **The clinician must rely on a collection of findings from multiple diagnostic modalities to detect both anatomic and pathophysiologic abnormalities**. Perhaps, the greatest challenge lies in differentiating constrictive pericarditis from restrictive cardiomyopathy.

1. **Electrocardiography.** Low voltage is frequently seen with **generalized flattening of the T waves**. There may be **left atrial enlargement. Atrial fibrillation** is a common finding.
2. **Chest radiograph.** Pericardial calcification is relatively common in advanced disease. The calcification is usually best appreciated with a lateral film and frequently involves the right ventricle and atrioventricular groove. **Pleural effusions** occur frequently, and there may be evidence of both **left and right atrial enlargement**.
3. **Two-dimensional echocardiography**
   a. **Septal bounce.** This is the **sudden cessation of septal motion**, as the heart abruptly stops filling upon meeting the rigid pericardium.
   b. **Ventricular interdependence.** This is due to the fixed space in which cardiac filling occurs. Preferential filling of the right ventricle on inspiration causes the septum to move to the left, whereas on expiration the augmentation of LV filling causes the septum to move to the right.
   c. **Inferior vena cava (IVC) plethora.** IVC is typically dilated and does not collapse, due to elevated right-sided pressures.
4. **Doppler echocardiography.** Although imaging findings may suggest pericardial constriction, most of the findings described previously are relatively low in sensitivity and specificity. Doppler assessment of diastolic flow patterns and the respiratory changes in these patterns may provide **significant evidence for the presence of constrictive physiology** and assist in helping **exclude competing diagnoses**, such as restrictive cardiomyopathy.
   a. **Respiratory variation in mitral and tricuspid flows.** In constrictive pericarditis, the thickened pericardium isolates the cardiac chambers from respiratory changes in intrathoracic pressures.
      (1) During **inspiration**, the drop in intrathoracic pressure is transmitted to the pulmonary veins, but not to the left ventricle. This reduces the pressure gradient required for diastolic filling of the left ventricle; therefore, a **decrease in mitral flow is observed during inspiration**. Conversely, there is an **increased tricuspid flow during inspiration. Findings suggestive of constrictive physiology include the following**:
         (a) **Mitral valve inflow.** Peak E velocity decreases by 33% or greater (Fig. 40.2).
         (b) **Tricuspid valve inflow.** Peak E velocity increases by 44% or greater and peak A velocity increases by 38% or greater (Fig. 40.3).
      (2) **Opposite changes are seen with expiration.** Increased intrathoracic pressure is transmitted to the pulmonary veins and this increases the driving pressure for LV filling. There is a **decreased tricuspid flow. The wide respiratory variation in peak E velocities helps to differentiate constrictive pericarditis from restrictive cardiomyopathy, in which *minimal* respiratory variation occurs** (Figs. 40.2 and 40.3).
   b. **Pulmonary venous flow.** In a healthy individual, pulmonary venous flow consists of a peak velocity during ventricular systole (S wave) and a smaller peak velocity during ventricular diastole (D wave). There is normally little respiratory variation in these velocities. In constrictive pericarditis, there is an increase in early diastolic flow manifested as a larger D wave; therefore, the **pulmonary systolic/diastolic (S/D) flow ratio is decreased**. In addition, **both systolic**

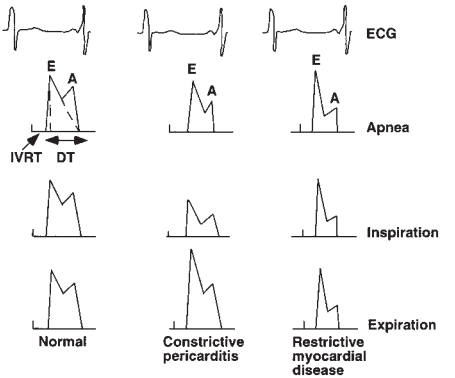

FIGURE 40.2 Respiratory variation in flow across the mitral valve in normal circumstance, constrictive pericarditis, and restrictive cardiomyopathy. The peak early diastolic filling velocity is denoted as E and the peak late diastolic filling velocity (from atrial contraction) is denoted as A. The isovolumic relaxation time (IVRT) is the period between aortic valve closure and mitral valve opening. The deceleration time (DT) is the time it takes to go from peak E velocity to cessation of flow. In constrictive pericarditis, expiration results in a decreased IVRT and a marked increase in peak E and peak A velocities across the mitral valve. Similar changes are not observed in normals and those with restrictive disease. Patients with restriction have an increased E/A and shortened DT; however, there is no significant respiratory variation. ECG, electrocardiogram. Adapted from Klein AL, Cohen GI, Pietrolungo JF, et al. Differentiation of constrictive pericarditis from restrictive cardiomyopathy by Doppler transesophageal echocardiographic measurements of respiratory variations in pulmonary venous flows. *J Am Coll Cardiol.* 1993;22:1935–1943.

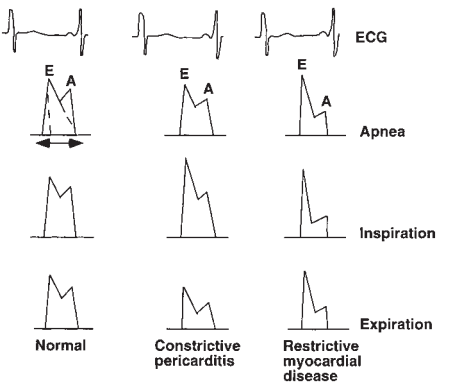

FIGURE 40.3 Respiratory variation in flow across the tricuspid valve in normal circumstance, constrictive pericarditis, and restrictive cardiomyopathy. Constrictive pericarditis results in changes in flow across the tricuspid valve that are opposite to those described for the mitral valve in Figure 40.2. In constrictive pericarditis, inspiration results in increased peak E and peak A velocities across the tricuspid valve. Similar changes are not observed in normals and those with restrictive cardiomyopathy. Patients with restriction have an increased E/A and shortened DT; however, there is no significant respiratory variation. ECG, electrocardiogram. Adapted from Klein AL, Cohen GI, Pietrolungo JF, et al. Differentiation of constrictive pericarditis from restrictive cardiomyopathy by Doppler transesophageal echocardiographic measurements of respiratory variations in pulmonary venous flows. *J Am Coll Cardiol.* 1993;22:1935–1943.

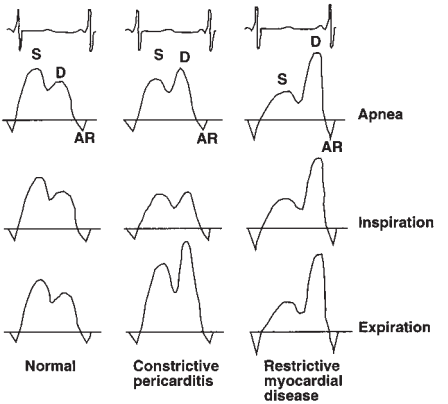

FIGURE 40.4 Respiratory variation in pulmonary venous flow in normal circumstance, constrictive pericarditis, and restrictive cardiomyopathy. The peak pulmonary venous velocities during systole are denoted as the S wave and peak diastolic velocities are denoted as the D wave. The AR wave represents the small reversal in flow that is noted with atrial contraction. In constrictive pericarditis, there is a slight decrease in the S/D ratio and a marked increase in both velocities during expiration as compared with inspiration. This respiratory variation in pulmonary venous flows is not observed in normal individuals or those with restrictive disease. Adapted from Klein AL, Cohen GI, Pietrolungo JF, et al. Differentiation of constrictive pericarditis from restrictive cardiomyopathy by Doppler transesophageal echocardiographic measurements of respiratory variations in pulmonary venous flows. *J Am Coll Cardiol.* 1993;22:1935–1943.

and diastolic pulmonary venous flows are markedly increased during *expiration*. This increase in expiratory pulmonary venous flow assists in distinguishing constrictive pericarditis from restrictive cardiomyopathy (Fig. 40.4).

c. Respiratory variation in hepatic vein flow. Hepatic venous flow reflects right-sided filling in much the same manner that pulmonary venous flow reflects left-sided filling. It is represented similarly by an S wave and a D wave, as well as a reversal in flow in atrial systole (AR wave) and a reversal in flow due to late ventricular systole (VR wave). Individuals with constrictive pericarditis and those without have a more prominent systolic flow than a diastolic flow; however, individuals without constrictive pericarditis have little respiratory variation in these flow velocities. **In constrictive pericarditis, there is a marked increase in the D wave during inspiration and a significant blunting during expiration. Expiration also results in prominent diastolic flow reversal demonstrated by increase in AR and VR.** In restrictive disease there is a reversal in systolic-to-diastolic flow ratios, but no respiratory variation exists in these flow velocities (Fig. 40.5).

d. Doppler tissue imaging

(a) Myocardial relaxation, and thus annular velocity, is typically **reduced in restrictive cardiomyopathies**, but the Doppler velocities of the medial mitral valve annulus in early diastole are **normal or slightly increased** in constrictive pericarditis. The pattern of these velocities is altered in constrictive pericarditis (Fig. 40.6). In normal individuals, peak early diastolic annular tissue velocity (E′) at the lateral mitral annulus is higher than that at the medial mitral annulus. **This relationship between the lateral and medial mitral annuli is reversed ("annulus reversus") in constriction, where E′ at the lateral mitral annulus is typically lower than E′ at the medial mitral annulus.** This is attributed to tethering of the LV lateral free wall to the pericardium in constriction. Similar effects of perimyocardial tethering on the RV free wall have been reported. These patterns

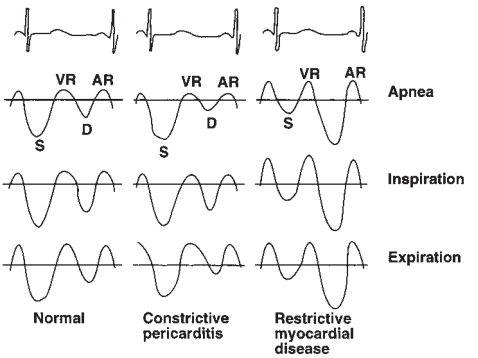

FIGURE 40.5 Respiratory variation in hepatic vein flow in normal circumstance, constrictive pericarditis, and restrictive cardiomyopathy. Similar to pulmonary vein flow, the S wave represents peak systolic flow velocity and the D wave represents peak diastolic flow velocity. VR denotes the reversal in flow noted in late systole, and AR is the reversal in flow due to atrial contraction. In both normal subjects and those with constrictive pericarditis, there is an increase in both S and D waves with inspiration. During expiration, there is little change in normal subjects; however, those with constrictive pericarditis will have a marked drop in both S and D waves and an increase in both VR and AR. Adapted from Klein AL, Cohen GI, Pietrolungo JF, et al. Differentiation of constrictive pericarditis from restrictive cardiomyopathy by Doppler transesophageal echocardiographic measurements of respiratory variations in pulmonary venous flows. *J Am Coll Cardiol*. 1993;22:1935–1943.

may not occur in all cases of constrictive pericarditis because of the heterogeneity of tethering (annular sparing constriction) and coexisting myocardial disease.

(b) In restrictive cardiomyopathies, the early diastolic annular velocity is characteristically **low at both medial and lateral mitral annuli** (< 8 cm/s).

5. **Cardiac catheterization.** The hemodynamics obtained in the catheterization laboratory assists in both diagnosing constrictive pericarditis and differentiating it from restrictive cardiomyopathy. In general, both right and left heart catheterization are performed to obtain simultaneous ventricular pressure readings.

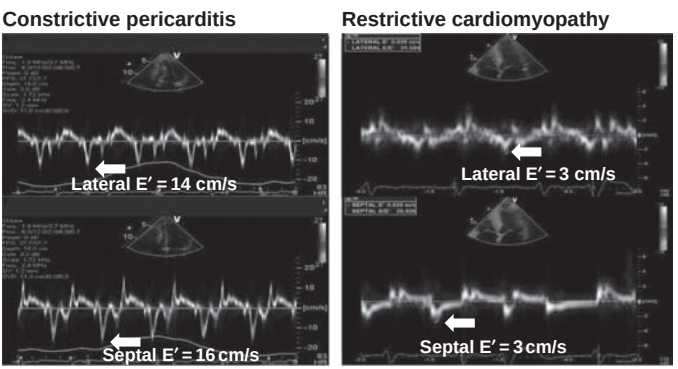

FIGURE 40.6 Annular tissue velocities from two patients. Note that tissue velocities are lower in restrictive cardiomyopathy compared with constrictive pericarditis. In addition, lateral E′ is lower than septal E′ in constrictive pericarditis, which is attributable to perimyocardial tethering of the lateral left ventricular free wall.

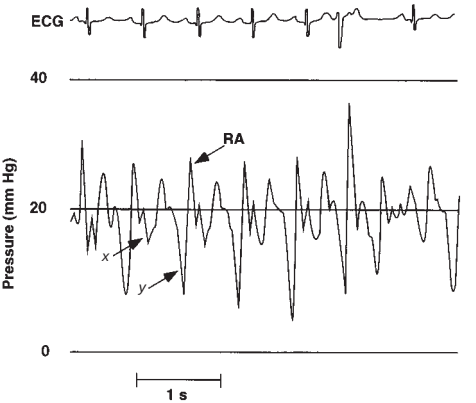

FIGURE 40.7 Right atrial (RA) pressure waveform in constrictive pericarditis. The preserved *x* descent and the prominent *y* descent contribute to the classic W-shaped atrial waveform. Adapted from Lorell BH, Grossman W. Profiles in constrictive pericarditis, restrictive cardiomyopathy and cardiac tamponade in cardiac catheterization. In: Baim DS, Grossman W, eds. *Angiography and Intervention*. 5th ed. Baltimore, MD: Williams & Wilkins; 1996:801–822. ECG, electrocardiogram.

a. Atrial pressures. The right atrial pressure waveform has been described as having a **W-shaped configuration**. This morphology is produced by a prominent *a* wave as the atria contract against an elevated ventricular pressure, an exaggerated *x* descent, and a steep *y* descent, due to rapid ventricular filling in early diastole (Fig. 40.7).

b. Ventricular pressures

(1) Ventricular pressure waveforms demonstrate the classic **dip-and-plateau** physiology, commonly referred to as the **square root sign** (Fig. 40.8).

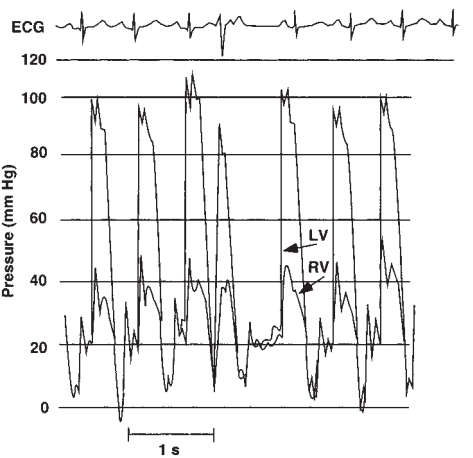

FIGURE 40.8 Right and left ventricular waveforms in constrictive pericarditis. Note the equalization of left ventricular and right ventricular end-diastolic pressures, generally within 5 mm Hg of one another. The rapid early diastolic filling and subsequent abrupt cessation of flow due to the rigid pericardium produces a dip-and-plateau waveform (square root sign), appreciated best in this waveform following the premature ventricular contraction. LV, left ventricular; RV, right ventricular; ECG, electrocardiogram. Adapted from Lorell BH, Grossman W. Profiles in constrictive pericarditis, restrictive cardiomyopathy and cardiac tamponade in cardiac catheterization. In: Baim DS, Grossman W, eds. *Angiography and Intervention*. 5th ed. Baltimore, MD: Williams & Wilkins; 1996:801–822.

(2) The initial downward deflection reflects the drop in pressure during the isovolumetric relaxation period. The subsequent upward deflection reflects early diastolic filling. The terminal plateau represents the cessation of flow that occurs once the limit of the rigid pericardium has been reached.

(3) The end-diastolic pressures of both ventricles are not only elevated but also equal, with a < 5 mm Hg difference between the two. The RV systolic pressure is generally < 55 mm Hg, with an RV end-diastolic pressure that is one-third greater than the RV systolic pressure. **These findings assist in differentiating constrictive pericarditis from restrictive cardiomyopathy, where RV systolic pressure is often elevated to > 55 mm Hg.**

(4) **Meticulously performed cardiac catheterization can demonstrate ventricular interdependence, which is a hallmark of constrictive pericarditis and is most useful in differentiating constrictive pericarditis from restrictive cardiomyopathy**. The ratio of the RV to LV systolic pressure–time area during inspiration versus expiration (systolic area index) has been shown to be a useful measure of enhanced interventricular interaction (Fig. 40.9).

(5) **Hypovolemia can mask characteristic features of constrictive pericarditis, and fluid challenge in the cardiac catheterization laboratory may be required to unmask ventricular interdependence in patients who are volume depleted**.

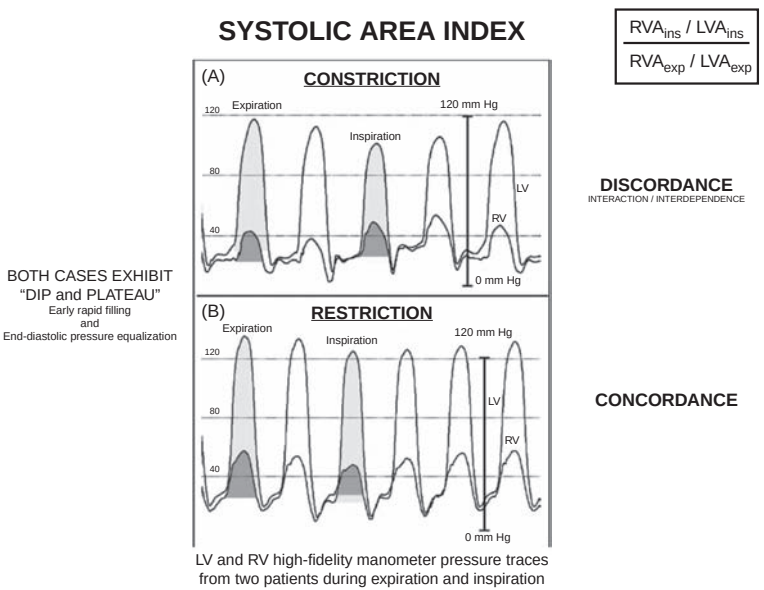

FIGURE 40.9 Respiratory ventricular interaction between RV and LV systolic area indexes in patients with constriction (A) and restriction (B). Note that in constrictive pericarditis patients (A), there is a rise in the area of RV pressure curve (darker-shaded area) and reduction in the area of LV pressure curve (lighter-shaded area), whereas in restrictive cardiomyopathy patients, there is a drop in the area of RV pressure curve during inspiration, with no change in the area of LV systolic pressure curve. LV, left ventricular; RV, right ventricular. RVA_{ins}, RV systolic area in inspirations; RVA_{exp}, RV systolic area in expirations; LVA_{ins}, LV systolic area in inspirations; LVA_{exp}, RV systolic area in expirations; Adapted from *J Am Coll Cardiol.* 2008;51:315-319.

(6) Role of cardiac CT and MRI in constrictive pericarditis

(a) Cardiac CT in constrictive pericarditis provides a superior three-dimensional delineation of the pericardium in comparison with echocardiography. A thickened pericardium > 4 mm is supportive of the diagnosis, although normal pericardial thickness does not exclude constrictive pericarditis. In a series reported by Talreja et al., (1) 18% of constrictive pericarditis patients had normal pericardial thickness. Cardiac CT is the best modality for assessing pericardial calcification, which may assist in surgical planning.

(b) Cardiac magnetic resonance imaging (CMR) provides both anatomical and hemodynamic information in constrictive pericarditis, without the radiation exposure that is associated with cardiac CT. Like echocardiography, MRI may demonstrate features of ventricular interdependence such as septal bounce and respirophasic variation in septal excursion. In addition, MRI is the best modality to assess pericardial inflammation, where an initial trial of medical therapy may be considered. Furthermore, MRI is excellent at tissue characterization, quantifying LV and RV systolic function, which is of value in patients where there is diagnostic uncertainty and restrictive myocardial disease is a consideration. CMR should be the non-invasive imaging modality of choice in a patient who is suspected to have constrictive pericarditis but has a nondiagnostic echo. The main limitation of MRI is that it cannot be performed in patients with MRI-incompatible implants or devices. MRI is also inferior to cardiac CT in assessing pericardial calcification.

(7) Differentiating constriction from restriction

In clinical practice, it is often challenging to differentiate constrictive pericarditis from restrictive cardiomyopathy, as both present as heart failure with preserved ejection fraction. Poor LV filling in constrictive pericarditis results from external constraints of a rigid pericardium, whereas a small LV cavity with impaired LV relaxation is usually the cause of diastolic dysfunction in restrictive cardiomyopathy. It is critical to differentiate between the two because of the different treatment strategies. Constrictive pericarditis is a potentially curable disease, whereas treatment options in restrictive cardiomyopathy are often limited to medical therapy. Despite the hemodynamic similarities, there are several key findings by echocardiography, cardiac catheterization, and CMR that can be used to differentiate these two clinical entities and are described in Table 40.4.

(8) Practical approach to diagnosing constrictive pericarditis

Basic workup of a patient with clinical features of constrictive pericarditis includes ECG and chest x-ray, which may reveal calcification. This should be followed by comprehensive echocardiography with a respirometer. If there is evidence of calcification on x-ray and echocardiography and there are convincing features of calcific constrictive pericarditis, then the patient may be directly referred to a cardiac surgeon. Some surgeons desire a preoperative right heart catheterization not only to confirm the diagnosis but also to get an accurate assessment of the cardiac index, which may assist in surgical planning. CMR should be strongly considered in cases where the echocardiogram is nondiagnostic and in patients where transient constriction is suspected. CMR will not only confirm the diagnoses of constrictive pericarditis but also assess pericardial inflammation. There is emerging evidence supporting medical therapy with anti-inflammatory medication as an initial strategy in a patient with inflamed constrictive pericarditis or effusive–constrictive disease. Cardiac CT should be limited to patients who

TABLE 40.4 Key Findings Used to Differentiate Constriction from Restriction

Investigation	Constrictive pericarditis	Restrictive cardiomyopathy
Echocardiography		
Annular tissue velocity (E′)	Preserved except at lateral mitral annulus and right lateral tricuspid annulus	Reduced
Diastolic dysfunction	Present	Present
Respirophasic interventricular septal shift	Present	Absent
Respirophasic variation in transvalvular/hepatic vein flow	Present	Absent
LV wall thickness	Normal	Normal or increased
Perimyocardial slippage (motion of LV, RV, and atrial free wall)	Reduced	Normal or reduced
Cardiac catheterization		
Elevated LVEDP	Present (equalization of diastolic pressures in all four chambers that are more suggestive of constriction)	Present
LV/RV discordance	Present	Absent
Cardiac MRI		
Respirophasic shift of interventricular septum	Present	Absent
Pericardial thickening or enhancement	Normal or increased	Normal
Myocardial scarring detected by post-gadolinium enhancement	Absent unless coexisting cardiomyopathy	Present

LV, left ventricular; RV, right ventricular; LVEDP, left ventricular end-diastolic pressure; MRI, magnetic resonance imaging.

are unable to undergo CMR or cases where three-dimensional assessments of pericardial calcification are warranted for surgical planning.

E. Therapy. Pericardiectomy is preferred in most cases, although there are certain patient populations in which medical therapy is appropriate.

1. Medical therapy

a. Patients who have NYHA class I symptoms may initially be treated with diuretics and a low sodium diet. One case series of 36 patients demonstrated resolution of pericardial constriction with the use of NSAIDs, colchicine, and/or steroids. However, most of these patients ultimately require pericardiectomy.

b. Medical therapy is also appropriate in **patients with severe comorbid illnesses** that limit life expectancy and/or place them at an unacceptably high risk for operative mortality. In addition trial of medical therapy maybe appropriate in inflammatory constrictive pericarditis.

2. **Surgical therapy**
   a. The treatment of choice is pericardiectomy. More than 90% of patients will report symptomatic improvement following the procedure.
   b. However, pericardiectomy carries an **operative mortality** that is reported to range from **5% to 20%**. The etiology of constrictive pericarditis can predict perioperative mortality. Patients who have constriction due to viral or idiopathic pericarditis have better outcomes than those who have radiation-induced constriction. Those patients with a poor preoperative functional class are at highest risk for perioperative death; therefore, most physicians advocate **early surgical intervention**.

IV. PERICARDIAL EFFUSION is a common clinical entity that is routinely diagnosed using echocardiography. It may be asymptomatic or present as life-threatening tamponade. **The presenting syndrome depends on the volume, the rate of accumulation, and the characteristics of the fluid**. Large effusions may be found unexpectedly and be asymptomatic, whereas rapidly accumulating small effusions may result in tamponade. An unstretched pericardium accommodates only 80 to 200 mL of rapidly accumulating fluid, without a significant change in hemodynamics. In contrast, the pericardial space may accumulate up to 2 L of fluid without any hemodynamic or clinical sequelae if this occurs slowly. **Compressive physiology** may occur with rapid accumulation of smaller amounts of fluid if the pericardium is stiff from fibrosis or infiltration by a tumor.

A. Clinical presentation

1. Slowly developing pericardial effusions, with no elevation of intrapericardial pressures, are **usually asymptomatic**.
2. Patients may complain of a **constant dull ache or pressure in the chest**.
3. There may also be a variety of symptoms from the space-occupying effects of the pericardial fluid on other organs in the chest. These include **dysphagia** from esophageal compression, **dyspnea** from lung compression and atelectasis, **hiccups** from compression of the phrenic nerve, and **nausea and abdominal fullness** from pressure on adjacent abdominal organs.
4. Large volume effusions may be associated with muffled heart sounds, Ewart's sign (dullness to percussion, bronchial breath sounds, and egophony below the angle of the left scapula), and rales in the lung field secondary to compression.
5. **Sinus tachycardia and hypotension are signs of hemodynamic compromise.**
6. **Patients with tamponade will have a pulsus paradoxus > 10 mm Hg**. The total intrapericardial volume is fixed; therefore, during inspiration, filling of the right ventricle pushes the septum into the left ventricle. This impairs left-sided filling, and there is a drop in systolic pressure during inspiration. Pulsus paradoxus is **not specific to cardiac tamponade** but may be seen in severe obstructive pulmonary disease, RV infarction, pulmonary embolism, or asthma.
7. Patients with tamponade will have jugular venous distention, and the *x* descent is typically the predominant waveform. **Beck's triad** includes jugular venous distention, distant heart sounds, and hypotension.

B. Etiology. Any cause of acute or chronic pericarditis (Table 40.5) may lead to the development of a pericardial effusion. Common causes of large chronic effusions include idiopathic pericarditis, uremia, pericarditis from malignancy or myxedema, congestive heart failure, nephrotic syndrome, cirrhosis, hypothyroidism, postcardiac surgery, and certain medications.

C. Laboratory examination and diagnostic testing

1. **Electrocardiogram.** The classic electrocardiographic finding consists of a **low-voltage tracing. Electrical alternans** is a marker of a massive pericardial effusion.
2. Chest radiography. **Increase in cardiothoracic ratio may occur if > 250 mL of fluid has accumulated. Increase in cardiothoracic ratio** with a large prominent superior vena cava, azygous vein, and decreased pulmonary vascularity should suggest the diagnosis of pericardial effusion.

TABLE 40.5 Causes of Pericardial Effusion (*Continued*)

Polyarteritis nodosa	Hydralazine
Scleroderma	Heparin
Dermatomyositis	Warfarin
Sarcoidosis	Phenytoin
Inflammatory bowel disease	Phenylbutazone
Whipple's disease	Cromolyn sodium
Behçet's syndrome	Dantrolene
Reiter's syndrome	Methysergide
Temporal arteritis	Doxorubicin
Amyloidosis	Penicillin
Familial Mediterranean fever	Minoxidil
Drugs	Colony-stimulating factor
Procainamide	Interleukin-2

3. Transthoracic echocardiogram (TTE) is the **modality of choice** for diagnosing and following pericardial effusions. It allows for accurate diagnosis, ensures the adequacy of drainage procedures, and enables a qualitative assessment in following pericardial effusions. Echocardiography is **not** useful in differentiating among the different etiologic factors.

a. Two-dimensional echocardiographic findings are as follows:

(1) An **echo-free space** is found between the visceral and parietal pericardium in both systole and diastole.

(2) The **motion of the parietal pericardium is decreased**.

(3) When the effusion is large, the **entire heart swings in the pericardium**. This swinging or rocking may occur along both the anteroposterior and the mediolateral axes of the heart, and it is thought to be the mechanism for electrical alternans seen on the ECG.

b. The Doppler echo findings in cardiac tamponade are described subsequently.

(1) Small effusions (< 100 mL) tend to localize at the posterior wall distal to the atrioventricular ring. These tend to be < 1 cm in width.

(2) Moderate effusions (100 to 500 mL). A moderate effusion could also be classified as one that surrounds the heart **but is 1 cm or less at its greatest width**.

(3) Large effusions (> 500 mL). Here, although the posterior accumulation continues, the heart seems to settle posteriorly with a greater expansion of the pericardial space laterally, apically, and anteriorly. The **effusion is > 1 cm at its widest point**.

c. The following may mimic a pericardial effusion on two-dimensional echocardiography.

(1) Pericardial fat tends to be **localized anteriorly**. Unless loculated, a pericardial effusion localized to the anterior wall is very rare.

(2) Seventy percent of **pericardial cysts** are found adjacent to the right cardiophrenic junction and adjacent to but separate from the right atrium in the apical four-chamber view.

(3) A pleural effusion can be differentiated from a pericardial effusion by virtue of the **position of the descending thoracic aorta in the parasternal long-axis view**. If the fluid is based in the pericardium, the aorta is displaced posteriorly to the effusion, away from the posterior wall of the left atrium. If the fluid is pleural based, the aorta retains its position immediately below the left atrium. Lung parenchyma may be seen in the pleural fluid.

(4) Other mimics of pericardial effusions are pericardial fibrous bands and pericardial calcification, anterior mediastinal tumors, peritoneal fluid, and a giant left atrium.

4. **Magnetic resonance imaging.** Although not usually required, MRI offers high sensitivity in the detection of pericardial effusions. It outlines the distribution and provides an estimate of the pericardial fluid volume that correlates well with echocardiography. It is very effective in facilitating detection of loculated pericardial effusions and pericardial thickening. Because of its high tissue contrast, MRI allows the visualization of the pericardium in multiple planes. It can also differentiate simple from complex effusions and pericardial fat from pathologic thickening.
5. **Computed tomography.** Using high-resolution axial images, CT provides excellent visualization of the pericardium. The size and distribution of the pericardial effusion are easily obtained using this technique. Moreover, differentiation among blood, exudate, chyle, and serous fluid may be achieved owing to the different attenuation coefficients for these substances.
6. Diagnostic pericardiocentesis and pericardial fluid examination should be considered in patients with large effusions without clear etiology. Aspirated pericardial fluid should be carefully inspected and immediately placed in sterile tubes for biochemical, microbiologic, and cytologic examination.

D. Therapy. The management of pericardial effusions depends on the underlying etiologic factor, volume, and hemodynamic significance.

1. **Pericardiocentesis** (see Chapter 69). Although the cause of the effusion is important, it can often be determined without pericardiocentesis by virtue of the clinical, systemic, and laboratory features of the presenting condition.
   a. Pericardiocentesis is **indicated if malignant, bacterial, mycobacterial, or fungal pericardial effusion is suspected**.
   b. **Pericardiocentesis is an indication in the setting of large pericardial effusion with associated pericardial tamponade (see subsequent text)**.
   c. With large effusions of recent onset, close clinical and echocardiographic follow-up is warranted. Pericardiocentesis **may be warranted in large asymptomatic pericardial effusions** when there are echocardiographic features of early tamponade.
2. Anticoagulation is best avoided until the effusion has resolved.

V. Cardiac tamponade occurs when an increase in pericardial fluid raises intrapericardial pressure and impairs diastolic filling. Cardiac tamponade is characterized by **elevated intracardiac pressures, a progressive limitation of ventricular diastolic filling, and a reduction in cardiac output**.

A. Pathophysiology

1. There appears to be an **inverse relationship between the volume of the pericardial effusion and the cardiac output once a critical volume is reached**. Beyond this, small increments in pericardial volume result in large increases in intrapericardial pressure. This critical volume depends on the compliance of the pericardium, the rate of fluid accumulation, and the status of the pericardial lining (infiltrations, calcification, or fibrosis).
2. The raised intrapericardial pressure results in a **decreased transmural distending pressure that results in decreased diastolic filling**.

3. The **cardiac output is initially maintained** by a heightened adrenergic tone, resulting in a resting tachycardia and peripheral vasoconstriction.
4. In severe tamponade, the compensatory mechanisms fail, resulting in a decreased cardiac output. Reduced coronary perfusion may cause subendocardial hypoperfusion, further compromising the stroke volume and the cardiac output. The finite space around the heart chambers also results in the equalization of filling pressures with that in the pericardium.
5. Following cardiac surgery, localized **pericardial hematoma** rather than fluid may impair filling of the heart. This most commonly occurs around the right atrium, is easily overlooked, and is difficult to diagnose using TTE. TEE should be considered in cases where **pericardial hematoma** is suspected but TTE images are nondiagnostic.

B. Clinical presentation. The signs and symptoms of cardiac tamponade all reflect a low cardiac output: **restlessness, agitation, drowsiness, or stupor; decreased urine output; dyspnea; chest discomfort and syncope or near syncope;** and **weakness, anorexia, and weight loss with a chronic effusion**.

1. **Physical findings**
   - **(a)** Raised central venous pressure. Characterized by a prominent *x* descent and an attenuated or absent *y* descent.
   - **(b)** Tachypnea. Reflects elevated pulmonary venous pressure.
   - **(c)** Tachycardia. Compensatory due to the low output state.
   - **(d)** Diminished heart sounds. Decreased transmission through the fluid-filled pericardium. A pericardial friction rub may be present in some cases.
   - **(e)** Pulsus paradoxus as described previously.
   - **(f) Hypotension (in severe cases)**.

C. Laboratory examination and diagnostic testing

1. TTE should always be performed when the diagnosis of cardiac tamponade is suspected. An echocardiogram may suggest findings consistent with cardiac tamponade, but the clinical diagnosis requires **synthesis of both bedside and echocardiographic findings**.
   - **a.** Echocardiographic signs of cardiac tamponade include the following:
     - **(1) Pericardial effusion**.
     - **(2)** Right atrial diastolic collapse typically begins in late diastole and continues into ventricular systole. It is best seen in the parasternal short-axis view, the subcostal view, and the apical four-chamber view. It is a **very sensitive sign, but its specificity is 82%,** with a positive predictive value of 50%. **The longer the duration of diastolic collapse, the more specific it is for tamponade**.
     - **(3)** RV early diastolic collapse (or RV diastolic inversion). **Although very sensitive in medical patients, it is less so in surgical patients due to the loculated nature of these effusions and the presence of adhesions**. When present, the collapse is described as a persistent posterior or inward movement of the RV free wall in diastole. It is seen most commonly in the anterior RV free wall and infundibulum with patients in the supine position. The parasternal long-axis and short-axis views of the heart are the best for evaluating this sign; M-mode recording through the right ventricle helps to outline the timing and duration of the event. **Isolated RV diastolic collapse appears to occur before the onset of clinical tamponade**. Conditions that raise RV intracavity volume and RV pressure (pulmonary hypertension, RV hypertrophy, and RV infarction) delay the occurrence of RV diastolic collapse until higher intrapericardial pressures are reached.
     - **(4)** Left atrial diastolic collapse—a rare but specific sign of tamponade.
     - **(5)** Abnormal inspiratory increase of **RV dimensions** with abnormal inspiratory decrease of LV dimensions.
     - **(6)** Respiratory variation in atrioventricular valve flow pattern, with an abnormal inspiratory increase in tricuspid valve flow and abnormal

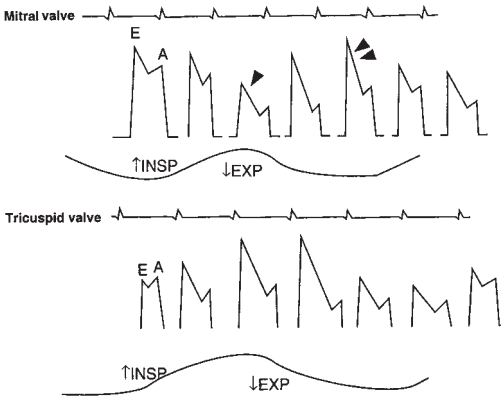

FIGURE 40.10 Pulsed wave Doppler for the mitral and tricuspid valves in a patient with cardiac tamponade. Note the marked respiratory variation of the inflow pattern, which in tamponade is a typical physiologic finding. INSP, inspiration; EXP, expiration.

inspiratory decrease in mitral valve flow (Fig. 40.10). Normally inspiration causes a decrease in mitral valve flow of up to 10% and an increase in tricuspid valve flow of up to 7%. **A decrease of the transmitral E wave of > 25% on inspiration is highly suggestive of significant tamponade**. A reduction of the tricuspid E wave of > 40%, together with prominent hepatic venous flow reversal during expiration, also suggests tamponade.

(7) IVC plethora. Failure to decrease the proximal diameter by at least 50% on sniff or deep inspiration has 97% sensitivity but only 40% specificity for tamponade physiology.

2. TEE is indicated in the postoperative patient with clinical signs of tamponade and inadequate surface images or in whom fluid is not present in the pericardium. TEE is highly sensitive for detecting hematoma in this setting.
3. Right heart catheterization is not necessary in patients for whom clinical and echocardiographic findings are consistent with tamponade and, in fact, may produce a delay in definitive treatment. However, right heart catheterization may be helpful in certain "borderline" cases for confirmation of the diagnosis of tamponade, quantitation of the hemodynamic compromise, and continuous assessment following pericardiocentesis. This is especially the case if pericardiocentesis is technically challenging.
   a. The **hemodynamic findings** include **equalization (within 4 mm Hg) of the right arterial pressure, pulmonary capillary wedge pressure (PCWP), pulmonary artery diastolic pressure, and RV middiastolic pressure**, which are raised usually between 10 and 30 mm Hg; the right arterial pressure reveals a **preserved *x* descent with an absent or attenuated *y* descent**; during expiration, the PCWP is slightly greater than the intrapericardial pressure that promotes filling of the left heart. With inspiration, the PCWP decreases (transiently), rendering a low or negative pressure gradient between the pulmonary venous circulation and the left heart.
   b. Following pericardiocentesis, there is an initial decrease in all pressures (right atrial, RV diastolic, intrapericardial, PCWP, and LV end-diastolic). As the intrapericardial pressures continue to fall below the right atrial pressure, the *y* descent recovers to baseline. This may take as little as 50 mL of fluid

aspiration, due to the steep nature of the pressure–volume curve of the pericardium. These changes are accompanied by an increase in blood pressure and abolition of the pulsus paradoxus. Only with adequate hemodynamic monitoring, including arterial line and right heart catheterization, can these changes be followed. Lack of fall in atrial pressures post pericardiocentesis may indicate an effusive–constrictive process.

c. **Effusive–constrictive pericarditis** (constrictive epicarditis). Effusive–constrictive pericarditis has been described in patients with pericardial tamponade in whom intracardiac pressures remain elevated despite the relief of intrapericardial pressure post pericardiocentesis. Effusive–constrictive pericarditis is unique, as there is predominant involvement of visceral pericardium (epicardium), called constrictive epicarditis by some authors. Some patients may have resolution with a conservative approach but others require extensive epicardiectomy, which should be performed at experienced centers as it is technically challenging.

D. Therapy

1. **Priority of therapy.** Once the diagnosis of tamponade is made, one needs to consider immediate **drainage**. The timing and method of drainage ultimately depend on the etiology of the effusion, the patient's level of acuity, and the availability of trained physicians. The options include needle pericardiocentesis and surgical drainage (subxiphoid pericardiectomy, pericardial window, and subtotal pericardiectomy).
2. **Medical therapy.** Optimal medical management is important and includes volume expansion, inotropic support if the patient is hypotensive, and avoidance of diuretics or vasodilators.
3. **Percutaneous therapy**
   a. Pericardiocentesis allows the rapid drainage of pericardial fluid. Advantages are that it **can be performed quickly, is less invasive than other drainage methods, and requires minimal preparation**. Complications include laceration of the heart, coronary arteries, or lung. There is also the possibility of recurrent effusions or incomplete drainage. Pericardiocentesis is not recommended for small (< 1 cm) effusions or for those characterized by loculation, adhesions, or fibrinous stranding (see Chapter 69).
   b. Percutaneous balloon pericardiotomy is a technique involving balloon dilation of the pericardium after securing access to the pericardial space with a transcutaneous approach. It has been used for large pericardial effusions, particularly when caused by malignancy.
4. **Surgical therapy.** Surgical drainage allows for a more complete drainage and is preferred if there is a high likelihood of recurrence. In addition, a surgical approach permits direct examination of the pericardium and access to the pericardial tissue for histopathologic and microbiologic diagnoses and has the capability to drain loculated effusions. Surgical drainage is associated with more pain, a longer recovery time, and more periprocedural morbidity.

CHAPTER 41

Parag R. Patel

Cardiac Tumors

I. INTRODUCTION. Cardiac neoplasms are **rare** in comparison with other forms of heart disease. Although secondary tumors of the heart are by definition malignant, primary tumors may be either benign or malignant. **Primary cardiac tumors occur approximately 30 times less frequently than cardiac metastases**. In most autopsy studies, the reported prevalence of primary tumors of the heart ranges from 0.001% to 0.03%, and about 75% are benign. Despite the relatively low prevalence, advances in curative operative therapy have made antemortem diagnosis of these tumors more clinically relevant.

II. CLINICAL PRESENTATION. Cardiac tumors often present with very nonspecific signs and symptoms. Patient complaints may be attributable to constitutional manifestations, embolic phenomena, or direct cardiac invasion/mass effect.

A. Constitutional symptoms. Many tumors, especially myxomas, are associated with a wide variety of systemic manifestations. Fever, chills, malaise, cachexia, and weight loss are not uncommon. Corresponding laboratory abnormalities, including leukocytosis, thrombocytosis or thrombocytopenia, hypergammaglobulinemia, as well as elevated erythrocyte sedimentation rate and C-reactive protein levels are frequently present as well. These findings are likely attributable to the constitutive production of **inflammatory cytokines** by the tumor or due to release from tumor necrosis. Myxoma cell production of **interleukin-6** and elevation of **antimyocardial antibodies** have been documented, with levels of these serum markers normalizing after tumor resection. Not surprisingly, patients with cardiac tumors often carry an incorrect antecedent diagnosis of collagen vascular disease, chronic infection, or noncardiac malignancy.

B. Embolic phenomena. Tumor embolization may account for the initial presenting symptoms, via either direct embolization of tumor fragments or thromboemboli released from the tumor surface. The type of emboli is dependent on tumor **location** as well as the presence of intracardiac shunts. **Right-sided** tumors, and left-sided tumors with left-to-right shunts, result in pulmonary emboli and if untreated may result in cor pulmonale. It may be difficult to clinically differentiate pulmonary tumor emboli from those due to venous thromboembolic disease. Chest radiography is usually not helpful. However, noninvasive imaging often has two unique characteristics that help differentiate tumor emboli from venous thromboemboli. First, tumor emboli may result in completely unilateral defects. Second, defects caused by tumor emboli generally do not resolve with time. **Left-sided** tumor emboli may result in visceral infarction, limb ischemia, myocardial infarction, or transient ischemic attack/stroke. In addition, multiple vascular aneurysms may develop. Of the benign primary cardiac tumors, embolization is most frequently noted with cardiac myxomas and even more so if the tumor has a villous surface. The brain is the most common site for systemic embolization in primary cardiac neoplasms, involving both hemispheres in approximately 40% of cases. Embolic findings in a young

person, in sinus rhythm and without valvular disease or endocarditis, should raise suspicion for the presence of an embolic source related to an intracardiac tumor.

C. Direct cardiac invasion/mass effect. Signs and symptoms are governed by tumor location and size. Intramyocardial tumors, which are most often found in the left ventricular free wall and intraventricular septum, generally remain asymptomatic when the tumor size is small but can result in arrhythmias, conduction abnormalities, and sudden cardiac death if they become larger. Impaired ventricular performance may mimic restrictive or hypertrophic cardiomyopathy. Rarely, ventricular rupture has been the initial presentation. Tumors of the left atrium, especially if mobile, may prolapse into the mitral valve, resulting in obstruction of atrioventricular (AV) blood flow. This results in signs and symptoms similar to mitral stenosis, such as dyspnea, orthopnea, paroxysmal nocturnal dyspnea, edema, and fatigue. Importantly, **syncope and sudden death** may also occur.

III. PHYSICAL EXAMINATION. Physical examination may show signs of pulmonary venous congestion. A fourth heart sound (S_4) may be present, as may a widely split, **loud first heart sound** (S_1). The loud S_1 is caused by late closure of the mitral valve, when the left ventricular–left atrial pressure crossover occurs at a higher pressure. Although this finding is also seen with mitral stenosis and preexcitation, the absence of a diastolic rumble or a short PR on an electrocardiogram should raise the possibility of left atrial tumor. Left atrial tumor may cause a holosystolic murmur at the apex radiating to the axilla (if tumor causes mitral incompetence) as well as diastolic murmur if the tumor obstructs mitral outflow. If the tumor obstructs the AV valve, a **presystolic crescendo murmur** may be present, which typically begins during ventricular systole as the tumor moves through the mitral orifice. This finding is present in approximately one-half of all patients with myxoma. The pathognomonic **tumor plop** manifests as an early diastolic sound, after an opening snap but before a third heart sound (S_3). Tumors of the **right atrium** often result in systemic venous congestion. Once significant pulmonary hypertension occurs, **systemic hypoxia, clubbing, and polycythemia** may develop as a result of right-to-left shunting. Right atrial tumors and intracavitary **right ventricular** tumors may present as right heart failure. A diastolic rumble that varies with inspiration may be noted and is due to tricuspid valve obstruction. The **P_2** is delayed and may have varying intensities. Jugular venous pressure waveform examination may demonstrate **prominent** a **waves and Kussmaul's sign**. Recurrent pulmonary emboli can potentiate pulmonary hypertension. **Left ventricular** tumors, when not intramural, typically result in signs and symptoms of pulmonary venous congestion or low-output states. Upon examination, findings may mimic aortic stenosis, subvalvular stenosis, or hypertrophic cardiomyopathy.

IV. DIAGNOSIS. Because no clinical sign or symptom is specific, more advanced diagnostic methodology is universally required.

A. Electrocardiography (ECG). In isolation, ECG provides little added clue to the diagnosis. However, changes in rhythm or voltage or development of new AV block on serial tracings may be the first sign of either extension of a primary cardiac tumor or development of secondary cardiac involvement.

B. Radiography. Chest radiography may be helpful in identifying epicardial tumors. Cardiomegaly, mediastinal widening, or cardiac silhouette irregularities may suggest the diagnosis. Calcifications are seen occasionally. Pulmonary congestion or oligemia may be noted in patients with large left or right intracavitary tumors, respectively.

C. Echocardiography. M-mode and two-dimensional echocardiography help establish the diagnosis in most patients. If a tumor is strongly suspected or a mass is noted by transthoracic echocardiography (TTE), transesophageal echocardiography (TEE) should be performed. TEE provides improved sensitivity (97% vs. 93% for TTE) and specificity, particularly with atrial masses, and allows for superior visualization of

anatomic details, such as contour, cysts, calcification, and presence of a stalk. Three-dimensional echocardiography is also increasingly helpful in evaluation due to its ability to visualize complex cardiac masses.

D. **Radionuclide imaging.** Although gated blood pool scanning has been used to identify cardiac tumors in the past, the inferior resolution and sensitivity have made this form of imaging uncommon in the workup. Positron emission tomography scanning is useful in identifying cardiac involvement in metastatic tumors and atrial myxomas.

E. **Computerized tomography (CT).** CT, especially multislice CT with contrast, is often used in the diagnosis and evaluation of cardiac masses. It can define tumor extension, although not as effectively as cardiac magnetic resonance (CMR), assess tumor calcification, and evaluate the adjacent extracardiac structures (pericardium and great vessels).

F. **Cardiac magnetic resonance.** Like CT, CMR has an important role in the evaluation of cardiac tumors. Specifically, it characterizes size, shape, and surface features, as well as evaluating tissue composition—giving information regarding the type of tumor that is present. Magnetic resonance imaging (MRI) has the highest soft tissue contrast of the imaging modalities, and it is particularly helpful in distinguishing thrombus from tumor. It is also the most sensitive imaging modality for detecting the extent of tumor infiltration.

G. **Angiography.** Cardiac catheterization is **not necessary in most cases**. However, in the following scenarios, the risk and cost of angiography may be worthwhile: clarifying inadequate noninvasive imaging, defining blood supply for suspected malignant tumors, and evaluating coexistent valvular or coronary artery disease that could alter surgical approach. The major additional risk of angiography is embolization of tumor or thrombus. A transseptal approach is relatively contraindicated in cases of suspected left atrial myxoma, given the high frequency of involvement of the fossa ovalis and the accompanying risk of embolization.

H. **Endomyocardial biopsy (EMB).** Limited data exist on the utility of EMB in the management of cardiac tumors. Generally, diagnosis is made from noninvasive imaging; however, EMB can be considered if imaging is equivocal or if a tissue sample is required prior to treatment decisions (i.e., chemotherapy).

V. PRIMARY CARDIAC MALIGNANCIES

A. **Benign neoplasms.** A description of specific benign cardiac tumors is given in subsequent text. Relative proportions are given in Table 41.1.

1. **Myxomas.** Most benign cardiac tumors are myxomas, accounting for approximately 30% to 50% in most series. For **sporadic myxomas**, which account for nearly 90% of all myxomas, about 65% of patients are female, with a mean age of 56 years. Eighty-six percent of sporadic myxomas are found in the left atrium and 90% are solitary masses. When multiple tumors are present, they are not necessarily limited to one chamber. The typical site of attachment within the left atrium is on or near the **fossa ovalis**. It is important to note that **tumors located on the posterior wall of the left atrium are usually not benign**. Less frequently, myxomas may be found in the right atrium, either ventricle, or arising from the AV valves. **Familial myxomas** comprise 4.5% to 10% of all cardiac myxomas. Although pathologically identical to sporadic myxomas, they have a number of unique clinical features. They have a well-characterized **autosomal dominant** transmission. They are often present within the construct of a larger syndrome. The **Carney complex**, or "syndrome myxoma," consists of both cardiac and noncardiac myxomas, spotty pigmentation (i.e., pigmented nevi), and endocrine overactivity (pituitary, adrenocortical, and endocrine testicular tumors). This may account for up to 7% of all cardiac myxomas. Patients with the Carney complex typically present in the third decade, often have bilateral tumors, and have high recurrence rates following resection. If a myxoma

TABLE 41.1 Relative Proportion of Benign and Malignant Tumors in Adults by Tumor Type

Benign tumor	% of group	Malignant tumor	% of group
Myxoma	46	Angiosarcoma	33
Lipoma	21	Rhabdomyosarcoma	21
Papillary fibroelastoma	16	Mesothelioma	16

Neurofibroma	1	Liposarcoma	1
Lymphangioma	1	Synovial sarcoma	1

AVN, atrioventricular nodal.

syndrome is suspected, **screening echocardiography is recommended** for all first-degree relatives, particularly if the index patient is young, has multiple tumors, or has typical noncardiac features of the genetic syndrome.

Pathologically, cardiac myxomas may be either smooth, round or gelatinous, or friable and irregular in appearance. They sometimes contain a hemorrhagic core and may attach via a sessile or pedunculated base. The typical diameter at presentation is 4 to 8 cm and the typical mass is 15 to 180 g. **Histologically**, myxomas have characteristic patterns of "lipidic" cells within glycosaminoglycan-rich myxoid stroma. **Ultrastructurally**, myxoma cells resemble embryonic mesenchymal cells. **Immunohistochemically**, they demonstrate variable activity for endothelial cell markers, with reliable positivity to vimentin, indicating a mesenchymal derivation. Myxomas also produce vascular endothelial growth factor, likely contributing to angiogenesis and tumor growth.

2. **Lipomas.** These benign tumors occur at **all ages,** with men and women affected equally. Tumors range in size depending on their location. Seventy-five percent of tumors are found in the subendocardium, whereas the remainder are subepicardial, intramuscular, or valvular. Many tumors are **clinically silent** and identified only at autopsy. Subendocardial tumors may result in symptoms related to cavity obstruction, whereas subpericardial tumors can lead to compression of the heart and/or development of pericardial effusion. Intramyocardial tumors may result in arrhythmias or conduction disturbances and possibly sudden death. Valvular lipomas can lead to valvular insufficiency and heart failure. Lesions are generally **well encapsulated** with a center of predominantly benign fatty cells. Without pathologic confirmation, lipomas can be confused with lipomatous hypertrophy of the interatrial septum. Both MRI and CT are useful in diagnosing cardiac lipomas based on the characteristic features of fatty tissue with these techniques.
3. **Papillary fibroelastomas.** The diagnosis of papillary fibroelastoma has increased with the more frequent use of TEE. They are the second most common primary cardiac tumors in adults and, grossly, these benign tumors resemble sea

anemones, with frondlike arms protruding off a central stalk. They are usually about 1 cm in length, single, and mobile in 40% of cases. The majority are located on the **ventricular surface of the aortic valve**, whereas the atrial side of the mitral valve is the second most common location. Rarely, they may present on the endocardial surfaces. Although these tumors are not associated with valvular dysfunction, in approximately 30% of cases, thrombus, with subsequent emboli, develops. Surgical resection is generally recommended for patients with a symptomatic presentation with embolization or in an asymptomatic patient with large, mobile tumors (1 cm or greater in diameter). Anticoagulation may be considered if recurrent embolization occurs in a nonsurgical candidate. Fibroelastoma may be differentiated from Lambl's excrescences by their location on noncontact areas of the valve.

4. **Rhabdomyomas.** Rhabdomyomas, the most common benign tumor in **children** and **infants**, are frequently located within one of the ventricles. These tumors are nearly always **multiple**, and the majority of patients have at least one intracavitary, obstructing lesion. The most common presentation for this type of cardiac tumor in adults is arrhythmia; however, it may be clinically silent if the tumors are small. There is a clear association with **tuberous sclerosis**: 80% of rhabdomyoma patients have the disease and 60% of tuberous sclerosis patients have rhabdomyomas. In some cases, rhabdomyomas may regress spontaneously during childhood.
5. **Fibromas.** Generally, fibromas are found in **pediatric** populations as well; these benign connective tissue tumors are almost universally **intramural**. They are usually firm, circumscribed but unencapsulated, and may grow to **several centimeters**. They have preponderance for the left ventricle and unlike rhabdomyomas do not spontaneously regress. The **Gorlin's syndrome** includes cardiac fibromas, multiple basal cell carcinomas, jaw cysts, and skeletal abnormalities.
6. **Hemangiomas/lymphangiomas.** These tumors are **very rare** and consist of benign collections of endothelial cells. Usually they are located within the intraventricular septum or AV node and as such may present as heart block, sudden cardiac death, or hemopericardium.

B. **Malignant neoplasms.** Histologically, **primary malignant tumors are virtually always sarcomas**. Suggestive **characteristics** include rapid growth, mediastinal invasion, hemorrhagic pericardial effusion, precordial pain, and pulmonary vein extension. Primary malignant neoplasms make up approximately 15% of all primary cardiac tumors.

1. **Angiosarcomas.** Almost always found within the right atrium, angiosarcomas, which include Kaposi's sarcoma, have a **2:1 male-to-female predilection** and are almost exclusively seen in adults. Hemorrhagic pericardial effusions are not uncommon. These tumors have ill-defined vascular channels lined with atypical endothelial cells. The blood flow through the tumor may produce a continuous precordial murmur. Despite resection and/or adjuvant therapy, clinical deterioration is rapid.
2. **Rhabdomyosarcoma.** Like angiosarcomas, these tumors of striated muscle are **more common in men**. However, there is no specific chamber that is preferentially affected. Tumors are generally infiltrative, but on occasion they may develop polypoid extensions, which can cause them to be mistaken for myxomas. Prognosis is poor.
3. **Mesothelioma.** The typical location of primary cardiac mesothelioma is the **pericardium**. Generally very diffuse, these tumors lead to symptoms consistent with pericarditis or hemorrhagic effusion. They may occasionally infiltrate the **AV node**, leading to conduction disturbances, sudden cardiac death, or tamponade. Much like cardiac sarcomas, these tumors carry a very poor prognosis.

4. **Other.** Fibrosarcomas, lymphosarcomas, liposarcomas, and other undifferentiated sarcomas represent the remainder of primary cardiac malignancies. These tumors are very rare and are generally infiltrative, involving multiple cardiac chambers. A clinical syndrome mimicking hypertrophic cardiomyopathy has been observed.

VI. SECONDARY CARDIAC MALIGNANCIES. As mentioned previously, most malignancies of the heart are secondary and, by definition, **metastatic**. The overwhelming majority of metastatic cardiac tumors occur in the **pericardium** and are usually **carcinomas**, as opposed to sarcomas. Due to increased prevalence, **the most commonly found metastatic tumor to the heart is lung cancer**. The typical presentation is of pericardial effusion or tamponade or pulmonary vein obstruction from direct extension. After metastatic lung cancer, breast cancer, lymphoma, leukemia, and renal cell carcinoma are the most common offenders. The tumor with **the greatest propensity to metastasize to the heart is melanoma**, followed by germ cell tumors and leukemia (Table 41.2). A new complaint referable to the heart in a patient with known extracardiac malignancy should prompt a thorough investigation to rule out cardiac malignancy. Unfortunately, prompt diagnosis usually does not favorably alter the prognosis.

VII. DIFFERENTIAL DIAGNOSIS. Establishing the correct diagnosis is imperative. A thorough differential diagnosis of **nonmalignant conditions** must be considered and ruled out. Possibilities include pericardial cysts, teratomas, lipomatous hypertrophy of the interatrial septum, thrombus, and sarcoid. Unfortunately, the final diagnosis in many cases must still be made pathologically.

VIII. THERAPY AND PROGNOSIS. The primary therapy for benign tumors remains **operative resection**, given the associated risk of lethal obstruction, arrhythmia, or embolization. Most surgeons perform excision with extracorporeal circulatory support in order to directly visualize the tumor, as well as a careful search for metasynchronous tumors. In higher risk patients, more extensive resection is recommended. The femoral or azygous vein is usually cannulated, as opposed to the right atrium, to avoid potential

TABLE 41.2 Metastatic Tumors to the Heart by Absolute Number and Greatest Propensity

Primary tumor	Absolute no.	Primary tumor	No. per 100 tumors
Lung	180	Melanoma	46
Breast	70	Germ cell	38

Sarcoma	24	Breast	10
Oral	22	Oral	9
Colon	22	Thyroid	9

tumor fragment embolization. Mitral valve repair or replacement is usually unnecessary in the absence of associated bacterial endocarditis. An analysis reviewing 106 operations for sporadic atrial myxomas noted only one perioperative death. Survival at 25 years is no different when compared with age- and sex-matched controls. There are limited data regarding the use of a minimally invasive or robotic approach to cardiac tumor resection. Small series suggest that parasternal or partial sternotomy access does not compromise the safety or efficacy while allowing for shortened hospitalization and better cosmetic results. Long-term follow-up is not yet available for this approach.

Regardless of the type of surgical resection or whether the tumor is sporadic, annual **follow-up noninvasive imaging is recommended** in all patients after resection. Recurrence rates of 12% to 22% have been quoted in patients with family histories, syndromes, and multiple tumors at original presentation versus 1% for patients with sporadic, isolated myxomas. Primary malignant tumors generally portend dismal prognoses. They are rarely cured by surgery because of the large amount of cardiac tissue involved. Adjuvant therapy (i.e., chemotherapy and radiation) after resection does not affect the prognosis, although it may slow progression in individual cases. **Palliative resection** is advocated for obstructive symptoms. **Cardiac transplantation** has been performed for patients with both benign and malignant tumors, but thus far, series have been too small to reliably predict outcomes.

ACKNOWLEDGMENTS: *The author would like to thank Drs. Adam W. Grasso and Nitin Barman for their contributions to earlier editions of this chapter.*

Saif Anwaruddin

Common Genetic Issues in Cardiovascular Disease

Genetic abnormalities have been associated with all types of cardiovascular disease, including coronary atherosclerosis, rhythm disorders, aortic disease, and structural heart disease. Since the initial descriptions of familial hyperlipidemia (FH) and the mutations in the low-density-lipoprotein (LDL) receptor (LDL-R), genetic studies have fostered an improved understanding of the underlying pathophysiology of various cardiovascular disease states. Furthermore, the sequencing of the human genome has ushered in the era of cardiovascular genomics. The ability to efficiently scour through the massive amount of genomic information will ultimately result in an improved understanding of the contributions of genetics to cardiovascular disease.

This understanding would potentially lead to an improved ability to accurately diagnose disease, prevent progression, and risk stratify at the individual level. Furthermore, this information will add to our understanding of the relationship between DNA variants and the response to drugs or other treatment modalities. The pharmacogenomic profiles developed may provide a refined approach to treatment with less toxicity. A more comprehensive assessment of future risk for both patient and potentially affected family members would also be feasible.

Although there are some examples within cardiovascular disease of simple monogenic disorders explained by principles of Mendelian inheritance, many of the entities, such as coronary atherosclerosis, acute myocardial infarction (MI), and atrial fibrillation (AF), are complex traits with multiple genes contributing to the phenotype. As opposed to Mendelian disorders, which are deterministic, complex traits are probabilistic.

It will require extensive time and effort to be able to define all the variations in all the genes that contribute to the susceptibility to or protection from a complex trait. Furthermore, the simple identification of genes involved does not address the issue of gene–gene and gene–environment interactions influencing complex traits. There have been extensive recent reports of genomic variants associated with risk of diseases. These variants are common, often accounting for 20% to 30% of the population attributable risk, but with an odds ratio of 1.2 or 1.3, for example, only 20% to 30% excess risk. These are common variants for common diseases. The hunt to find rare variants that induce susceptibility to common diseases with high risk (or protection) will be more challenging, but eminently feasible with sequencing technology and ultra high-throughput genotyping. At some point in the future, the major genomic underpinnings for most cardiovascular diseases will be known. Furthermore, the integration of all of the genomic variants for any cardiovascular disease has not been undertaken. What follows is a brief overview of what is known today about the genetic basis for a sampling of disease entities within cardiovascular medicine.

METHODOLOGY. The process of discovering relevant genetic underpinnings of generally complex traits requires an extensive analysis of genetic information in large populations. Complex traits without simple Mendelian patterns of inheritance are difficult to analyze, given that there are often multiple genes involved, with many gene interactions being important. However, even before attempting this task, perhaps the single most significant goal is to accurately and concisely define the phenotype in question. In addition, many variations

often exist within a single category of cardiovascular diseases such as hypertrophic cardiomyopathy (HCM) and acute MI. The ability to clearly define cases and controls is paramount to obtaining accurate and reproducible information.

There are three major methods of identifying DNA variants associated with cardiovascular disease. Of note, some of the single nucleotide polymorphism (SNP) variants that have been found are not in a gene, but actually in areas of the genome not associated with gene expression. It is not yet known how these variants exert their effect. Of note, the major variants for MI (at 9p21) and AF (at 4q25) fall into this category of intergene (i.e., not in a gene).

I. GENOME-WIDE ASSOCIATION STUDIES. Gene association studies utilize the concept that multiple SNPs, where a single nucleic acid substitution results in a different allele, can affect the risk of developing a disease in question. This is especially true in diseases of complex traits such as coronary artery disease (CAD) and MI. Using genes of interest in a particular disease phenotype, scans are conducted in areas of interest in both cases and controls to compare haplotype frequency to determine if a statistically significant difference between the two groups in the region of interest exists. One of the limitations of this technique is the inability to know whether the SNP of interest is involved in the pathogenesis or simply associated (in linkage disequilibrium) with another SNP that may actually be involved in the process. Utilizing this process of gene association across the entire genome is now possible with high-throughput sequencing technology of up to 1 million SNPs assessed per individual and the term "genome-wide" association has been coined. The SNPs assessed are tagging tiny bins of the genome, such that in a genome of an individual of European ancestry, there are only about 250,000 bins, most of which are sampled by current high-throughput genotyping. Each bin is typically inherited as a block (haplotype). The breakdown of the genome into bins via the International Haplotype map was critical in making current genome-wide association studies possible.

II. LINKAGE ANALYSIS. Linkage analysis is another tool used to identify genes that are possibly involved in the pathogenesis of complex traits. The use of linkage analysis begins without any assumptions as to the potential involvement of various genes. It is based on the idea that during the process of meiosis when recombination events occur, they tend to involve loci on a particular chromosome that are closer together than farther apart. By following the inheritance of certain known loci, assumptions can be made about the presence of alleles that cosegregate with them. Using linkage analysis, the potential exists to identify these known loci as markers and determine the transmission through a pedigree and its relationship to the phenotype in question. In doing so, it may be possible to suggest that an allele in proximity to known loci may be associated with a particular phenotype. The logarithm of odds ratio (LOD score) is used to estimate the (distance) relationship between the known locus of interest and an unknown locus thought to be associated with the disease phenotype. A LOD score of 3 is used to classify such a statistically meaningful linkage.

III. GENE EXPRESSION PROFILING. The identification of certain disease alleles or loci associated with disease-causing genes provides valuable information but remains limited in its scope. The statistical association of genes and disease **does not prove causation or even involvement** in disease. Gene expression profiling takes this concept one step forward in trying to delineate gene expression. The presence of transcription profiles may provide more useful information in terms of relevance of findings made in gene association studies or linkage analysis. Technology now permits the evaluation of large genomes in a rapid fashion to derive expression profiles, which can then be compared between diseased and healthy individuals to draw conclusions about which genes are transcriptionally active in certain phenotypes.

A. Coronary atherosclerosis and atherothrombosis. Coronary atherothrombosis and atherosclerosis remain significant causes of morbidity and mortality in the population as a whole. There is a great deal of variation in presentation in atherosclerosis and in acute MI. The presence of atherosclerosis is necessary but not sufficient

for atherothrombosis. There are separate factors involved that predispose to plaque rupture and thrombosis. Even within the category of plaque rupture, the clinical phenotypes vary significantly, as reflected by the spectrum of diseases that constitute the acute coronary syndromes. These entities are complex traits and are influenced by multiple pathways. Inflammation, endothelial dysfunction, and dyslipidemias are only a few of the pathways influencing the development of atherothrombosis and atherosclerosis. Delineating the genetic basis, in most cases, is a work in progress, but it may help to broaden our understanding of the disease.

1. **Dyslipidemia: familial hyperlipidemia and other genetic variants.** Dyslipidemia is a known risk factor for the development of atherosclerosis. Familial hyperlipidemia (FH) is a well-characterized, albeit relatively uncommon, entity defined by elevated levels of serum LDL levels, which predispose to coronary atherosclerosis. Often, these patients can develop atherosclerotic disease between 20 and 30 years of age. In FH, the dyslipidemia is often severe and not responsive to standard lifestyle and pharmacologic interventions.
   a. **Autosomal dominant.** The underlying problem in this form of FH has to do with an abnormality in the clearance of the *LDLR* gene, and, as a consequence, elevated levels of LDL persist. The *LDLR* gene located at 19p13.2 has approximately 1,600 known mutations, and these appear to affect many aspects of LDLR function. Alterations in the gene range from point mutations to gene rearrangements. homozygotes and heterozygotes for FH vary in terms of the severity of lipid levels. The majority of individuals are heterozygous, and those with homozygous patterns of inheritance are more severely affected. Typically, these patients and affected family members develop premature coronary atherosclerosis and MI.
   b. **Autosomal recessive.** This occurs as a result of a mutation in the low-density-lipoprotein receptor adaptor protein 1 (*LDLRAP1*) gene at 1p36-p35. The phenotype of this form of FH is milder than the autosomal dominant form of the disease and more amenable to treatment with lipid-lowering agents.
   c. **Familial defective apolipoprotein B.** The cellular mechanisms involved in cholesterol metabolism are complex, and there are many potential targets where mutations can significantly affect phenotype. One such example is a point mutation in the apolipoprotein B (apo B) component of the LDL molecule. The Arg3500Gln is the most common substitution in the apo B (*APOB*) gene and results in the inability of LDL to bind to its LDLR. This mutant allele is more common in Northern European populations as a cause of hyperlipidemia, but the phenotype appears to be less severe than in the familial hyperlipidemia caused by *LDLR* mutations.
   d. **Proprotein convertase subtilisin/kexin type 9 *(PCSK9)*.** Less than 5% of FH involves *PCSK9* gene, located at 1p32.3, responsible for increasing degradation of the LDL receptor. Mutations in *PCSK9*, such as D374Y, F216L, S127R, D129N, D374H, N425S, and R496W, confer gain in function and cause FH. Much rarer *PCSK9* mutations are those that result in loss of function and act to reduce serum cholesterol levels, thereby conferring a protection against coronary atherosclerosis. Many new *PCSK9* mutations have been identified, but their effect on *PCSK9* functions requires further investigation.

   In addition to the FH syndromes, there is a multitude of genes involved in more frequently occurring types of dyslipidemia. Phenotypically, these forms of dyslipidemia are less severe and more amenable to treatment than those observed in the FH population.
2. **Endothelial function.** *MEF2a* is a transcription factor that localizes to the endothelial cell of coronary arteries and is believed to be important in the function of endothelial cells. In 2003, a mutation in the *MEF2a* gene was described in a large family with autosomal dominant transmission of coronary atherothrombosis.

A 21-bp deletion in exon 11 was thought to result in loss of function. Three additional variants in the *MEF2A* thought to be associated with MI and CAD have also been reported. The findings from a large Spanish case-controlled study provided supporting evidence for only one of these variants, P279L. Further studies have failed to replicate these mutations in association with MI. The 21-bp deletion has not been found in any family apart from that in the original study. This particular mutation may be a "private mutation" for the family in the original study and therefore extremely difficult to replicate. In 2008, Lieb et al. (1) conducted a large German study, with 23 MI families, > 1,700 MI patients, and 2 large control populations, and did not find any evidence that the *MEF2A* gene had any linkage or association with MI/CAD.

3. **Inflammation.** The genes *ALOX5AP* (arachidonate 5-lipoxygenase–activating protein) and *LTA4H* (leukotriene A4 hydrolase) encode proteins involved in the leukotriene pathway, particularly in the synthesis of the proinflammatory leukotriene B mediators. The case for inflammation as a significant participant in acute MI has been made stronger by the discovery, through linkage analysis to a locus at 13q12-13, of a four SNP haplotype (Hap A) in the gene *ALOX5AP*. Carriers of the variant had higher levels of leukotriene B4. This variant was found to double the risk of MI and to almost double the risk of stroke. Another haplotype variant (Hap B) of the *ALOX5AP* gene was found to confer a doubling of the risk of MI in a British cohort. In Italy, researchers identified an increased risk for CAD with Hap B only. In a large German study, presence of the haplotype B indicated an association with an increased risk of MI. These studies provide strong evidence of the role of *ALOX5AP* gene for increased CAD risk in Europeans. In a case–control study of a US Midwestern population with European American ancestry, seven SNPs in the *ALOX5AP* gene along with two haplotypes (Hap A and Hap B) were genotyped. The results indicated that Hap B and one of the SNPs (SG13S377) were significantly associated with increased risk of premature CAD. In a meta-analysis conducted in 2010, the Hap B and SNP (rs1722842) variants in the *ALOX5AP* gene were associated with coronary heart disease, while Hap A was associated with the risk of MI.

   The *LTA4H* gene encodes leukotriene A4 hydrolase and is also involved in the inflammation pathway. A haplotype (HapK) in the *LTA4H* gene moderately increased the risk of MI in a cohort from Iceland. A moderate risk was also found in studies of three US cohorts with European Americans, but HapK, although rarer in African Americans, tripled their risk of MI. The results of these studies with the ALOX5AP and the LTA4H variants provide the basis for further research to develop new drugs targeting the leukotriene pathway, thereby preventing or reducing the risk of MI and CAD in the future.

B. Connective tissue abnormalities and disease of the aorta. Genetic mutations affecting the connective tissue and extracellular matrix typically affect multiple organ systems, but often the most devastating and lethal effects arise from those upon the cardiovascular system. Aortic dissection and rupture are often the consequences of such abnormalities, and what follows is a brief description of three such disorders.

1. **Marfan syndrome.** This disorder is inherited in an autosomal dominant fashion with variable penetrance, and it affects the connective tissue, leading to abnormalities of organs of the cardiovascular, skeletal, and ocular systems. The genetic defect is in the **fibrillin-1 (*FBN1*) gene on chromosome 15q21**. Often, the diagnosis is made on clinical grounds alone. The classic features of tall stature, arachnodactyly, dolichostenomelia, pectus excavatum, ectopia lentis, and a positive family history all support a diagnosis of Marfan syndrome. The cardiovascular system is affected, and the most common cause of death in these patients is from aortic dissection and aortic rupture. Other common related problems include aortic dilation, aortic valve regurgitation, mitral valve prolapse (MVP), tricuspid valve prolapse, and arrhythmias. When patients with Marfan syndrome present with dissection, they are typically younger and do not have hypertension.

The *FBN1* gene is responsible for producing a key constituent of microfibrils, which are important in the extracellular matrix. Microfibrils add to the elastic properties of extracellular tissue. Over 1,000 mutations in the *FBN1* gene have been recognized and appear to affect different aspects of cellular processing of fibrillin-1. These mutations can vary from a SNP to a premature stop codon. There are no specific relationships between mutations and phenotypes as of yet. Family members with Marfan syndrome and **the same *FBNI* gene mutation may show wide variation in onset and severity of cardiac symptoms**. The diagnosis of Marfan syndrome is generally made on a clinical basis. However, genetic testing for Marfan syndrome is available.

2. **Ehlers-Danlos syndrome.** Ehlers-Danlos syndrome is a group of connective tissue disorders caused by defects in proteins that are involved in the formation of collagen. It is uncommon and has an autosomal dominant pattern of inheritance. There are multiple types of Ehlers-Danlos syndrome based on the collagen type affected; however, the cardiovascular system is involved prominently in type IV, the vascular type of Ehlers-Danlos syndrome. The gene, ***COL3A1*, involved in this subtype is localized to chromosome 2q24.3-q31 and encodes for type III procollagen**. Vascular complications include dissections of the carotids and the vertebral arteries. Aortic dissections are the primary cause of death and often involve both the thoracic and the abdominal aortas. Diagnosis is usually ascertained clinically along with genetic testing for evidence of the mutation in the *COL3A1* gene.
3. **Loeys-Dietz syndrome.** Loeys-Dietz syndrome is a connective tissue disorder characterized by hypertelorism, cleft palate, and vascular disease in the form of arterial aneurysms and dissection. It is inherited in an autosomal dominant pattern. Clinically, these patients are at high risk for aortic dissection. Loeys-Dietz syndrome is caused by **mutations in the transforming growth factor beta (TGF-β) receptors I and II genes (*TGFBR1* and *TGFBR2*) on chromosome 3**. Phenotypically, the characteristics are like those in Marfan syndrome, and also these patients appear similar (with the exception of the craniofacial abnormalities) to Ehlers-Danlos patients with vascular involvement (type IV). The relevance of this distinction is that those with Loeys-Dietz appear to have much lower intraoperative mortality during corrective vascular surgery. Genetic testing to identify the mutation is needed for definitive diagnosis, but it is not available in all laboratories.

C. Cardiomyopathies. Primary disease of the myocardium affects both systolic and diastolic function and often results in heart failure or other adverse events over time. Many of the nonischemic cardiomyopathies have a strong genetic component to explain their phenotype. Perhaps, the most clinically relevant entities include dilated cardiomyopathy (DCM) and HCM. Cardiomyopathies can also occur as a secondary process in response to a separate unrelated factor (i.e., hypertension), and it is unknown to what degree genetic susceptibility determines the myocardial response/remodeling over time. Until recently, the classification of cardiomyopathies has been based on the phenotype and morphologic characteristics. However, with an improved knowledge of the genetics of these disorders, a new understanding and appreciation for the underlying mechanisms of disease in these disorders will undoubtedly influence how these entities are treated in the future.

1. **Dilated cardiomyopathy.** DCM is characterized by dilation of one or both of the ventricular chambers resulting in severe systolic dysfunction and characterized by congestive heart failure. A genetic cause is thought to account for 20% to 50% of DCM cases, and in many cases, the pattern of inheritance is autosomal dominant. However, recessive, X-linked, and mitochondrial patterns of inheritance are also seen. Many cases of DCM are secondary to other etiologies. Mutations in more than 30 genes have been associated with this phenotype, and although the products of most of these genes are important structural proteins, there are others involved in the handling of calcium and regulation of energy within the myocytes. Again, however, there are often subtle differences in the

various types of DCM, such as age of onset and degree of clinical symptoms, all of which may suggest separate genetic abnormalities are at play. Mutations in the sarcomere protein genes account for approximately 10% of DCM. Mutations in *LMNA* gene, which encodes lamin A and lamin C, are seen in DCM with prominent conduction system disease. Although mutations in *SCN5A* are also associated with this type of DCM, the clinical picture differs as ventricular dysfunction is usually present. Dystrophin gene mutations are seen in X-linked DCM. Mutations in the *ALMS1* gene are transmitted in a recessive pattern, resulting in DCM with hearing loss. Genetic testing is available for many of the gene mutations that have been identified. Table 42.1 lists some of the genetic variants that are believed to be associated with various DCM phenotypes.

2. **Hypertrophic cardiomyopathy.** HCM (see Chapter 10) is a highly variable and heterogeneous disease process that affects the myocardium, with clinical manifestations varying from completely asymptomatic to severe (sudden cardiac death). The

TABLE 42.1 Genetic Variants Associated with Dilated Cardiomyopathy

Gene	Location	Mode of inheritance	Gene product and function
MYH7	14q11	Autosomal dominant	Sarcomere gene—encodes β-myosin heavy chain Mutations may affect contractile mechanism
MYH6	14q12	Autosomal dominant	Sarcomere gene—encodes α-myosin heavy chain Mutations may affect contractile mechanism
TNNT2	1q32	Autosomal dominant	Sarcomere gene—encodes troponin T type Mutations may affect contractile mechanism
ACTC1	15q11-q14	Autosomal dominant	Sarcomeric gene—encodes cardiac actin Vital part of contractile apparatus of myocyte
TMPO	12q22	Autosomal dominant	Encodes thymopoietin—maintains functional integrity of nucleus
CSRP3	11p15	Autosomal dominant	Encodes cardiac muscle LIM protein Functions as a stretch sensor in myocyte
Phospholamban (*PLN*)	6q22	Autosomal dominant	Controls muscle relaxation through calcium regulation via calcium ATPase
DES	2q35	Autosomal dominant	Encodes desmin—cytoskeletal protein involved in stabilization of sarcomere and mutation may affect contractile force
Presenilin (*PSEN1/2*)	14q24.3 (*PSEN1*) 1q31-q42 (*PSEN2*)	Autosomal dominant	*PSEN1* encodes presenilin 1 *PSEN2* encodes presenilin 2 Transmembrane proteins
Lamin A/C (*LMNA*)	1q22	Autosomal dominant	Encodes lamin A and lamin C Structural proteins—affect structure of nucleus in myocytes **DCM with prominent conduction system disease**
SCN5A	3p21	Autosomal dominant	Cardiac sodium channel gene **DCM with prominent conduction system disease**

TABLE 42.1 Genetic Variants Associated with Dilated Cardiomyopathy (*Continued*)

Gene	Location	Mode of inheritance	Gene product and function
Dystrophin (*DMD*)	Xp21.2	X-linked	Encodes dystrophin More commonly involved in Duchenne's and Becker's muscular dystrophy Mutations can affect transduction of contractile force **X-linked DCM**
ALMS1	2p13	Autosomal recessive	Alstrom syndrome 1 Causes with DCM and hearing impairment Encodes for protein associated with obesity and diabetes **Autosomal recessive DCM**

DCM, dilated cardiomyopathy.

broad range of phenotypes and significant selection bias resulted in an overestimation of the mortality rate associated with this disease. The clinical spectrum of the disease is wide, and the ability to accurately predict outcomes remains challenging. The clinical variability of HCM is not only limited to the presenting phenotype but also related to age of presentation, clinical course, and eventual outcomes, making it very challenging to properly identify a phenotype of interest. The characteristic phenotype is an asymmetrically hypertrophied myocardium with a small ventricular chamber and occasionally a left ventricular (LV) outflow tract (with systolic anterior motion of the mitral valve) and/or an intracavitary gradient.

More than 700 mutations in 13 separate genes have been identified, with the majority of mutations in 3 of the genes: *MYH7* on chromosome 14, *MYBPC3* on chromosome 11, and *TNNT2* on chromosome 1. The genes involved encode proteins of the cardiac sarcomere unit. The products of these genes involved include troponin T, troponin I, β-myosin heavy chain, myosin light chains, myosin-binding protein C, α-myosin light chain, α-tropomyosin, and actin.

The importance of properly characterizing a phenotype as heterogeneous as HCM has been illustrated by the example of glycogen storage diseases mimicking the appearance of HCM. Mutations in the genes for AMP-activated protein kinase gamma2 (PRKAG2) and lysosome-associated membrane protein 2 (LAMP2) were found in phenotypes that closely resembled HCM but were differentiated based on serum protein levels and ventricular preexcitation.

3. **Arrhythmogenic right ventricular cardiomyopathy/dysplasia.** Arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D) is a primary abnormality resulting in fibrofatty infiltration of the myocardium, primarily the right ventricle. Clinical manifestations include right ventricular dysfunction and lethal ventricular arrhythmias. Diagnosis often includes a battery of tests, including an electrocardiogram demonstrating repolarization abnormalities and an epsilon wave, magnetic resonance imaging or computed tomography demonstrating fibrofatty infiltration of the right ventricle, and endomyocardial biopsy. Often a positive family history of the disorder is present. ARVC/D can be inherited in either an autosomal dominant (in most cases) or autosomal recessive pattern. Mutations in 12 genes associated with ARVC/D have been identified. Mutations in genes encoding desmoplakin, desmoglein-2, cardiac ryanodine receptor, and plakophilin-2 have all been associated with the autosomal dominant form of the

disease. In ARVC12, mutations in the *JUP* gene, encoding junction plakoglobin, have an autosomal dominant pattern of inheritance, whereas mutations in the same *JUP* gene with an autosomal recessive inheritance result in Naxos disease, a variant associated with the triad of ARVC/D along with dermatological manifestations such as wooly hair and palmoplantar keratoderma. Twelve subtypes of ARVC/D are distinguished on the basis of the gene involved and are described further in Table 42.2.

4. **Left ventricular noncompaction.** Left ventricular noncompaction (LVNC) is a relatively rare congenital abnormality of the myocardium resulting in a trabeculated appearance of the LV cavity. It is characterized by spongy myocardium that results from arrest in endomyocardial morphogenesis. It is seen in < 1% of adults. This disorder can occur in isolation or in association with other congenital anomalies. Over time, it is thought that noncompaction can proceed to DCM with severe systolic dysfunction. Different genes are thought to be involved in the pathogenesis for each of the LVNC variants. A mutation in the α-dystrobrevin gene (*DTNA*) on chromosome 18 has been linked to left ventricular noncompaction-1 (LVNC1). A mutation for LVNC2 has been identified on chromosome 11p15 (LVNC2). LVNC3 is caused by mutation in the *ZASP* gene on chromosome 10q22.2-q23.3. LVNC variants have been mapped specifically to mutations of the sarcomere genes: LVNC4 is caused by mutation in the *ACTC1* gene (chromosome 15q14), LVNC5 is caused by mutation in the *MYH7* gene (chromosome 14q12), and LVNC6 is caused by mutation in the *TNNT2* gene

TABLE 42.2 Genetic Variants of ARVC/D

ARVC/D variant	Chromosome/ gene	Comments
ARVC/D1	14q23-24/*TGFβ-3*	TGFβ-3 involved in embryogenesis and cell differentiation
ARVC/D2	1q41.1-q43/*RYR2*	Ryanodine receptor involved in Ca^{2+} release into cytosol
ARVC/D3	14q12-q22	In 1996, discovered in a study of three small families
ARVC/D4	2q32.1-q32.3	Some family members from affected cohort had involvement of the left ventricle
ARVC/D5	3p25.1/*TMEM43*	TMEM43 is a transmembrane protein expressed in blood and cardiac tissue
ARVC/D6	10p14-p12/*PTPLA*	Protein tyrosine *phosphatases* involved in cell growth and *PTPLA* is primarily found in cardiac tissue
ARVC/D7	10q.22.3 2q35/*DES*	
ARVC/D8	6p24/*DSP*	Desmoplakin (DSP) is a constituent protein of desmosomes
ARVC/D9	12p11/*PKP2*	Plakophilins are part of desmosomes and are also found in the nucleus regulating transcription PKP2 encodes plakophilin-2, an essential armadillo repeat protein of the cardiac desmosome
ARVC/D10	18q12.1-q12/*DSG2*	Encodes for desmogleins involved in desmosome cell adhesion
ARVC/D11	18q12.1/*DSC2*	Encodes for desmocollin, a desmosomal cadherin protein
ARVC/D12	17q21/*JUP*	Encodes junctional plakoglobin/JUP

From OMIM Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim/).

(chromosome 1q32). There is also an X-linked form of LVNC (LVNCX) caused by mutation in the gene encoding tafazzin (TAZ) and allelic to Barth syndrome.

D. Arrhythmogenic disorders

1. **Brugada syndrome.** Disorders of the conduction system of the heart lead to significant clinical manifestations, most notably ventricular arrhythmias and sudden cardiac death. Two entities, long QT syndrome (LQTS) and Brugada syndrome, have been well described, and their respective genetic abnormalities have been characterized. Brugada syndrome was initially described by Josep and Pedro Brugada in 1992. Clinically, ventricular arrhythmias and sudden cardiac death occur, particularly in middle-aged men. Characteristic electrocardiographic features can help make the diagnosis, and, in some cases, certain drugs, including sodium channel blockers and tricyclic antidepressants, can unmask the abnormality on a surface electrocardiogram. **Brugada syndrome is typically inherited in an autosomal dominant pattern**. However, a de novo mutation can occur in approximately 1% of cases. Mutations in eight genes have been identified as causing Brugada syndrome: *CACNA1C*, *CACNB2, GPD1L, HCN4, KCNE3, SCN1B*, *SCN3B,* and *SCN5A.* The *SCN5A* gene has been mapped to chromosome 3p22.2 and is a voltage-gated sodium channel gene. *SCN1B* (chromosome 19q13.12) and *SCN3B* (chromosome 11q24.1) are also voltage-gated sodium channel genes. *GPD1L,* an NAD-dependent glycerol-3-phosphate dehydrogenase gene, is associated with chromosome 3p22.3. *HCN4*, on chromosome 15q24, is a hyperpolarization-activated cyclic nucleotide-gated potassium channel 4 gene. *KCNE3* (chromosome 11q13.4) is a voltage-gated potassium channel gene. *CACNA1C* (chromosome 12p13.33) and *CACNB2* (chromosome 10p12.33-10p12.31) are two subunits of the L-type voltage-dependent calcium channels. Genetic testing in Brugada syndrome is used to confirm a clinical diagnosis. A negative result does not necessarily exclude the diagnosis. It may reflect that the individual does not have the condition, but it may also mean that the individual either has a mutation in a gene not part of the testing panel or has a mutation in a Brugada-associated gene not included in the panel.
2. **Long QT syndrome.** LQTS encompasses a range of disorders characterized clinically by syncope and sudden cardiac death, with electrocardiographic abnormalities in the QT interval and in the T-wave morphology. LQTS is usually inherited in an autosomal dominant pattern. Recessive inheritance, seen in Jervell and Lange-Nielsen types 1 and 2, is rare. There are 12 different types of LQTS based on the type of gene involved. The various forms of LQTS are often distinguishable by clinical features and genetic abnormalities. One such distinguishing feature is that those with long QT syndrome 1 (LQT1) are typically at higher risk during periods of exercise, whereas those with the long QT syndrome 3 variant (LQT3) are at higher risk during sleep. The *KCNQ1* gene encodes the catecholamine-sensitive portion of the potassium channel responsible for conducting the delayed rectifier current (I_{Ks}) in the LQT1 variant, whereas the *SCN5A* gene is affected in the LQT3 variant. The underlying defect involving the sodium channel results in a prolonged depolarization current, whereas defects involving the potassium channel result in a longer QT duration secondary to inability to reestablish repolarization within the myocyte. The autosomal recessive phenotypes (Jervell and Lange-Nielsen types 1 and 2) are associated with bilateral sensorineural hearing loss.

   Hundreds of mutations are believed to be involved in LQTS. However, most of the prognostic information available is based on the gene involved and not the specific mutation. Having the genotypic information can help in prognosis and in determining response to therapy. The rates of ventricular arrhythmias and sudden cardiac death vary based on the gene involved, as does the response to therapy. This information may be particularly helpful in trying to decide between medical therapy, implantable cardioverter–defibrillator implantation, or both. Table 42.3 lists the 12 variants of LQTS and the genes involved.

TABLE 42.3 Genetic Variants Associated with Long QT Syndrome

LQT variant	Gene	Mode of inheritance	Function of gene product
LQT1	*KCNQ1*	Autosomal dominant	Catecholamine-sensitive portion of I_K potassium channel
LQT2	*KCNH2*	Autosomal dominant	α-Subunit of I_{Kr} potassium channel
LQT3	*SCN5A*	Autosomal dominant	Cardiac sodium channel
LQT4	*ANK2*	Autosomal dominant	Ankyrin protein
LQT5	*KCNE1*	Autosomal dominant	β-Subunit of I_{Ks} potassium channel
LQT6	*KCNE2*	Autosomal dominant	β-Subunit of I_{Ks} potassium channel
LQT7	*KCNJ2*	Autosomal dominant	Subunit of I_{Kr} potassium channel
LQT8	*CACNA1C*	Autosomal dominant	Subunit of the L-type voltage-dependent calcium channel
LQT9	*CAV3*	Autosomal dominant	Encodes caveolin-3, which is found in the membrane surrounding muscle cells *CAV3* gene mutations may affect the function of sodium channels
LQT10	*SCN4B*	Autosomal dominant	β-voltage–gated sodium channel subunit
LQT11	*AKAP9*	Autosomal dominant	Encodes the A-kinase anchor protein-9
LQT12	*SNTA1*	Autosomal dominant	Syntrophin, alpha 1 peripheral membrane protein associated with dystrophin, and dystrophin-related proteins
Jervell and Lange-Nielsen type 1	*KCNQ1*	Autosomal recessive	Subunit I_K channel
Jervell and Lange-Nielsen type 2	*KCNE1*	Autosomal recessive	β-Subunit of I_{Ks} potassium channel

3. **Atrial fibrillation.** AF is the most common of the arrhythmic disorders. The majority of adult-onset familial AF is inherited in an autosomal dominant pattern. A major breakthrough has occurred in the genomics of AF, with the finding that variants at **4q25 carry a risk of 1.6 and a population attributable risk of > 30%** in individuals of both European and Asian ancestries. The 4q25 variants are near a gene—*PITX2*—which is involved in left–right symmetry of the heart in development. It has not yet been proven how the variants at 4q25 exert their effect. Other genes contribute to a much smaller degree to the risk of AF. The majority of the mutations linked to AF have been found in the potassium ion channel genes (*KCNQ1*, *KCNJ2*, *KCNE2*, and *KCNH2*). The connexin 40 gene (*GJA5*) has also been implicated as a possible candidate. Due to the small number of mutations identified for familial AF, it is quite possible that there are many more mutations for familial AF that are still unknown. Genotype–phenotype correlations for familial types of AF have yet to be determined.

E. Valvular heart disease

1. **Mitral valve prolapse.** MVP (see Chapter 16) is a common disorder that appears to have a strong genetic component, and the familial form is likely inherited in an autosomal dominant pattern with variable penetrance. Although, in addition, it occurs in an idiopathic form, it is also associated with other valvular syndromes such as bicuspid aortic valve (BAV) and connective tissue diseases, which typically affect cardiovascular function such as Marfan syndrome, osteogenesis imperfecta, and Ehlers-Danlos syndrome. Prolapse of the mitral valve occurs primarily in the connective tissue matrix of the valve itself. Myxomatous degeneration of the valve tissue leads to redundant tissue and weakening of both the valve and the subvalvular apparatus. Clinically, this manifests as displacement of the mitral valve leaflets into the left atrium during systole and may progress to mitral regurgitation and eventual congestive heart failure with occasional rupture of the chordae. Although surgical repair and replacement have improved the long-term prognosis of this disorder, understanding the genetic basis of this disease may allow the earlier diagnosis and development of therapies to prevent progression.

   Three genes have been identified with MVP inherited in an autosomal dominant manner. These are *MMVP1* (chromosome 16p12.1-11.2), *MMVP2* (chromosome 11p15.4), and *MMVP3* (chromosome 13q31.1-32.1). X-linked myxomatous valvular dystrophy (XMVD) has been mapped to chromosome Xq28, and the filamin A gene (*FLNA*) has been identified as a cause of XMVD. Filamin A may also have a role in MVP.

2. **BAV and aortic valve calcification.** Aortic valve disease (see Chapter 15) can be divided into two different types based on clinical characteristics: BAV and calcific aortic valvular disease. Calcific aortic valvular disease is typically a disease of the elderly and appears to be affected by those risk factors predisposing toward CAD. Vitamin D receptor polymorphisms have been implicated in the genesis of degenerative aortic valve disease, as has the apo E4 allele of the apolipoprotein E allele. BAV disease is believed to be a congenital abnormality that is typically discovered earlier on in life and is associated with disease of the aorta. What these two disorders have in common is the eventual progression to calcification of the aortic valve itself. Mutations in the *NOTCH1* gene on chromosome 9 have been implicated in BAV development. NOTCH1 is a transmembrane protein with transcriptional regulatory activity that is vital not only for aortic valve development but also for calcification. It is thought that mutations in this gene may allow the normally repressed transcription factor Runx2 to facilitate the development of valvular endothelial cells into osteoblastlike cells and promote valvular calcification. Mutations in the *ACTA2* gene on chromosome 10q23.3, which codes for actin, have also been linked to BAV. Mutations in ubiquitin fusion degradation 1-like gene (chromosome 22) have also been implicated in BAV. This gene codes for a signaling protein that is prevalent during embryonic formation of cardiac outflow tracts. Three additional loci associated with BAV have been identified on chromosomes 5, 13, and 18, but no specific genes have been discovered.

F. Inborn errors of metabolism. Cardiovascular disease is often a manifestation of genetic abnormalities in separate pathways, which produce secondary effects upon the cardiovascular system. Many of these genetic mishaps occur in multiple pathways essential to metabolism, and their resultant phenotypes often impose upon the cardiovascular system. Table 42.4 lists some examples of metabolic abnormalities and the associated cardiac manifestations.

G. Chromosomal abnormalities and cardiovascular disease. Chromosomal abnormalities that occur at the time of development can have serious implications with regard to the proper growth and development of a child. Although neuropsychiatric development is often delayed, the cardiovascular system is also affected in many of

TABLE 42.4 Cardiovascular Manifestations of Systemic Metabolic Disease

Metabolic disorder	Gene/protein defect	Effect upon cardiovascular system	Comments
Anderson-Fabry disease	α-Galactosidase deficiency	Accumulation of globotriaosylceramide Cardiomyopathy in the form of LVH, lethal arrhythmias, and coronary ischemia	X-linked
Hereditary hemochromatosis	*HFE*, an MHC class I-like protein, ferroportin, hepcidin, hemojuvelin, and transferrin receptor-2	Iron deposition involves the heart and results in cardiomyopathy	Can be acquired via transfusion-associated hemochromatosis
Niemann-Pick disease	Defect in sphingomyelinase	Accumulation of sphingomyelin in cardiac tissue leading to cardiomegaly	Affected children do not survive past first few years of life
Hurler's syndrome (type 1 mucopolysaccharidosis)	Deficiency in α-L-iduronidase	Biventricular enlargement, endocardial fibrosis, and valvular disease	Autosomal recessive
Hunter's syndrome (type 2 mucopolysaccharidosis)	Deficiency in iduronate sulfatase	Cardiac involvement includes valvular disease	X-linked
Danon disease	Deficiency in lysosome-associated protein type 2	Cardiac involvement includes LVH, CHF, and preexcitation	X-linked
Gaucher's disease	Deficiency of glucocerebrosides	Accumulation of glucocerebroside leading to cardiomyopathy, also calcification of aorta and aortic and mitral valves	
Pompe disease	Defect in glycogen storage	Biventricular concentric hypertrophy	Autosomal recessive transmission
L-Carnitine deficiency	*OCTN2* gene mutations affecting transport of carnitine	Cardiomegaly and dilated cardiomyopathy	Carnitine transport is vital for mitochondrial function. Cardioprotective benefits may be derived from protection from free radical damage

LVH, left ventricular hypertrophy. MHC, major histocompatibility complex; CHF, congestive heart failure.

TABLE 42.5 Common Chromosomal Abnormalities and Associated Cardiovascular Disease

Syndrome	Chromosomal abnormality	Associated CV abnormality
Down syndrome	Trisomy 21	Endocardial cushion defect, mitral valve prolapse, and tetralogy of Fallot
Turner syndrome	45X	Coarctation of the aorta, bicuspid AV, and anomalous PV return
Patau syndrome	Trisomy 13	Dextrocardia, ASD/VSD, and bicuspid AV
Edwards syndrome	Trisomy 18	PDA and left SVC
Fragile X syndrome	*FMR1* gene (X chromosome) with trinucleotide repeats	Mitral valve disease

CV, cardiovascular; ASD, atrial septal defect; AV, aortic valve; PV, pulmonary vein; PDA, patent ductus arteriosus; SVC, superior vena cava; VSD, ventricular septal defect.

these disorders and often survival may be limited due to the severity of congenital defects. Table 42.5 lists common syndromes associated with chromosomal structural abnormalities and the associated cardiovascular findings.

Dyslipidemia

I. INTRODUCTION. Cardiovascular disease (CVD) is the leading cause of morbidity and mortality in the industrialized world. It is estimated that 30% of all deaths worldwide can be ascribed to cardiovascular causes, and this number is expected to rise further as the incidence of CVD in the developing world increases as a result of lifestyle changes.

A. Morbidity and mortality. CVD is the number one killer in the United States, accounting for 36% of all deaths. CVD is responsible for one death every 36 seconds and claims more lives each year than cancer, accidents, chronic obstructive pulmonary disease, and diabetes mellitus combined. One of every five deaths in the United States is caused by coronary heart disease (CHD). There are 15.8 million Americans with a history of myocardial infarction (MI) or angina pectoris. As many as 865,000 Americans have a new MI each year, and 164,000 are victims of sudden cardiac death. The average age at first MI is 65.8 years for men and 70.4 years for women. According to the Centers for Disease Control and Prevention, elimination of all forms of CVD would raise the overall life expectancy by 7 years.

B. Economic consequences of CVD. The economic burden of CVD and stroke in the United States was estimated to be $431.8 billion in 2007. In 2004, CVD was the leading cause of hospitalization, contributing to > 6.4 million patient discharges and 4.2 million emergency department visits.

C. Prevention of coronary artery disease (CAD). Table 43.1 shows important targets for secondary prevention among patients with known coronary or noncoronary vascular disease. The goals for primary prevention are similar, but the cost-effectiveness of medical intervention is not so favorable in all populations. The consequences of modest population-wide risk reduction (e.g., reduction in fat intake [currently 33% of total calories] and cholesterol levels) and lifesaving technologies (e.g., surgery, angioplasty, and coronary care units) have reduced the death rate and possibly contributed to reduced morbidity, but the burden of CVD remains a major challenge.

II. HYPERLIPIDEMIA. Dyslipidemia is an important **correctable predictive factor for CAD**. There is a strong, independent, continuous, and graded relation between total cholesterol (TC) or low-density lipoprotein cholesterol (LDL-C) level and risk of CAD events. This relation has been clearly demonstrated in men and women in all age groups. More than one-half of US adults (105 million) have TC levels > 200 mg/dL, and of these, 37 million have values > 240 mg/dL. In general, a 1% increase in LDL-C level leads to a 2% to 3% increase in risk of CAD.

A. Physiology

1. **Lipoproteins** are large molecular compounds that are essential to the transport of cholesterol and triglycerides within the blood. They contain a lipid core composed of triglycerides and cholesterol esters surrounded by phospholipids and specialized proteins known as **apolipoproteins**. The **five major families of lipoproteins** are **chylomicrons, very low density lipoproteins (VLDLs),**

TABLE 43.1 Goals for Secondary Prevention among Patients with Known Vascular Disease

Risk factor	Goal
Hypertension (mm Hg)	140/90 (130/80 if CKD or diabetes)
Dyslipidemia (mg/dL)	LDL < 100 (< 70 in high-risk patients)
	HDL ≥ 60
	Triglycerides < 100
Physical activity	30 min, three or four times per week
Body mass index	≤ 24.9 kg/m^2
Diabetes mellitus	Near-normal blood sugar (HbA1c < 6.5%)
Smoking	Complete cessation

CKD, chronic kidney disease; HbA1c, hemoglobin A1c; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

intermediate-density lipoproteins, low-density lipoproteins (LDL), and high-density lipoproteins (HDLs).

2. **Apolipoproteins** are necessary for the structure and enzymatic processes of lipids. Apolipoprotein A1 (**apo A1**) is a major component of **HDL**, and apolipoprotein B (**apo B**) is the main apolipoprotein for the remaining **non-HDL** lipoproteins.

B. Lipid-lowering trials. Aggressive lipid-lowering drug treatment of persons at various risk levels reduces CAD morbidity and mortality rates and increases overall survival. Although the association between hyperlipidemia and CAD was established much earlier, the demonstration of a relationship between reduction in serum lipid levels and a reduction in all-cause mortality had to await the development of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, or "statins." Multiple randomized trials have provided overwhelming evidence of the benefit of statins in both primary and secondary prevention of cardiovascular events.

1. **Primary prevention trials**
   a. The **West of Scotland Coronary Prevention Study (WOSCOPS) (1995)** demonstrated that treatment of men at relatively high risk with profoundly elevated cholesterol levels significantly reduced the risk of heart attack and death from heart disease. The double-blind study randomized 6,600 healthy men with a baseline mean LDL-C level of 193 mg/dL to pravastatin (40 mg/d) or to placebo, for an average of 5 years, and demonstrated a 31% relative reduction in the incidence of nonfatal MI or CAD death. Follow-up of this population published in 2007 showed that the statin group continued to experience lower rates of cardiovascular death after a further 10 years, even though only one-third continued to take statins during the additional follow-up period.
   b. The **Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) (1998)** demonstrated benefit among patients with more typical risk profiles, including lower cholesterol values, than among those in the WOSCOPS. AFCAPS/TexCAPS patients had a baseline mean TC level of 220 mg/dL. The study randomized 6,600 patients to lovastatin 20 to 40 mg daily or placebo and demonstrated a 36% relative risk reduction (RRR) for first acute major coronary events in the lovastatin group.
   c. The **Heart Protection Study (HPS) (2002)** randomized 20,536 subjects in a 2 × 2 factorial design to daily simvastatin (40 mg) or placebo and to antioxidants or placebo (the antioxidant arm did not show any benefit or harm).

The study focused on patients who were deemed high risk for CVD but not thought to merit treatment with statins based on the prevalent clinical practice at that time. Increased risk was defined as presence of or history of CAD, cerebrovascular disease, peripheral arterial disease, diabetes mellitus, or treated hypertension. Simvastatin therapy was associated with a 13% reduction in all-cause mortality, including an 18% reduction in coronary death rate. The beneficial impact of statin therapy was seen with respect to all cardiovascular end points, with significant reductions in risk of nonfatal MI, incidence of first stroke, and coronary and noncoronary revascularization. **Treating patients with LDL levels < 100 mg/dL was also associated with a beneficial reduction in vascular events**. The benefit was maintained in patients receiving other cardioprotective medications, such as angiotensin-converting enzyme inhibitors, β-blockers, and aspirin. Although not strictly a primary prevention trial, the HPS provided evidence to support treatment of risk as endorsed by the National Cholesterol Education Program (NCEP) guidelines. However, the HPS results refuted the threshold LDL level (as proposed by NCEP III at that time) below which statins were not previously indicated.

d. **Pravastatin in Elderly Individuals at Risk of Vascular Disease (PROSPER) (2002)** randomized 5,804 patients between the ages of 70 and 82 years to placebo or pravastatin. These patients had preexisting coronary, cerebral, or peripheral vascular disease or had a history of smoking, hypertension, or diabetes. The study demonstrated a 15% reduction in the composite of coronary death, nonfatal MI, and stroke over a period of 3 years. The study demonstrated efficacy of primary and secondary prevention in the elderly.

e. The **Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT-LLT) (2002)** randomized 10,355 hypertensive patients with one other coronary risk factor and a baseline mean LDL-C level of 148 mg/dL to pravastatin 20 to 40 mg/d or usual care. The study did not demonstrate a mortality difference in the two arms after a follow-up period of 4.8 years. This lack of observable difference in outcome might have resulted from the relatively modest LDL reduction (17% with pravastatin vs. 8% in usual care) or the fact that 26% of the patients in the "usual care" group were taking a statin at the end of the trial.

f. The **Anglo-Scandinavian Cardiac Outcomes Trial—Lipid-Lowering Arm (ASCOT-LLA) (2003)** randomized 10,305 patients with hypertension and at least three other cardiovascular risk factors and a baseline mean LDL-C level of 133 mg/dL to atorvastatin 10 mg/d or placebo. The study was stopped prematurely after a median follow-up of 3.3 years by the safety monitoring committee because of a significantly higher incidence of the primary end point (nonfatal MI or fatal CHD) in the placebo group. The study demonstrated a 36% RRR for the primary end point in the atorvastatin group compared with the placebo group. Further analysis demonstrated that the benefit of statin therapy started after only 1 year of treatment. There was also a significant reduction (RRR of 27%) in the incidence of fatal and nonfatal stroke in the atorvastatin group. This study, like the HPS, provided further evidence of the benefit of statins in patients at high risk for CVD without regard for baseline TC or LDL levels.

g. The **Collaborative Atorvastatin Diabetes Study (CARDS) (2004)** randomized 2,838 diabetic patients with one additional cardiovascular risk factor, no history of CVD, and an average baseline LDL-C of only 117 mg/dL to atorvastatin 10 mg/d or placebo. This study was also terminated prematurely owing to an excess incidence of the primary end point (a composite of acute coronary events, coronary revascularization, or stroke) in the placebo group after a median follow-up of 3.9 years. Overall, the atorvastatin group

had an RRR of 37% for the primary end point and 27% for all-cause mortality. The importance of this trial was its demonstration of the clinical benefit of statin use in diabetic patients regardless of baseline LDL-C level, making a compelling case for statin use in all diabetic patients with at least one additional cardiovascular risk factor. According to the NHANES III data, 82% of diabetic patients in the United States would meet the entry criteria for the CARDS trial.

h. The **Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) (2005)** trial focused on the prevention of CHD in patients with type 2 diabetes using fenofibrates. The study randomized patients with type 2 diabetes diagnosed after 35 years of age with no clear indication for cholesterol-lowering therapy at baseline to fenofibrate (200 mg/d) or placebo. The study failed to show a difference in the primary composite end point of CHD or nonfatal MI between the two groups at 5-year follow-up. However, several secondary end points were lower in the fenofibrate group including nonfatal MI and coronary revascularization.

i. **Japan EPA Lipid Intervention Study (JELIS) (2007).** The goal of this trial was to evaluate treatment with the fish oil supplement eicosapentaenoic acid (EPA) in addition to statin therapy compared with statin therapy alone among patients with hypercholesterolemia. The study randomized patients in an open-label manner to treatment with EPA (1,800 mg/d) in addition to statin therapy (pravastatin 10 mg/d) or simvastatin (5 mg/d) or to statin therapy alone. At a mean follow-up of 4.6 years, there was a significant reduction in the primary end point of major adverse cardiovascular events in the EPA plus statin group (2.8% vs. 3.5%). This was driven primarily by a significant reduction in rates of unstable angina and a trend toward lower rates of nonfatal MI and revascularization. No difference was seen in sudden cardiac death or fatal MI.

j. The **Justification for the Use of Statins in Primary Prevention: An Intervention Trial Evaluating Rosuvastatin (JUPITER) (2008)** trial focused on patients with normal LDL-C levels but increased levels of high-sensitivity C-reactive protein (CRP). This was the first clinical trial to demonstrate that statin therapy may benefit patients with low-to-normal LDL levels and no known CVD. The study randomized 17,802 healthy subjects with an LDL-C < 130 mg/dL and a CRP ≥ 2.0 mg/L to daily rosuvastatin of 20 mg or placebo. The trial was stopped early for a mortality benefit after a median follow-up of 1.9 years. The study demonstrated that after 1 year of therapy, there were lower levels of LDL-C (55 vs. 110 mg/dL) and lower levels of CRP (2.2 vs. 3.5 mg/L) in the rosuvastatin-treated group. There was also a lower incidence of the primary end point of nonfatal MI, nonfatal stroke, hospitalization for unstable angina, arterial revascularization procedure, or confirmed death from cardiovascular cause (0.77 vs. 1.36 events per 100 person-life years) as well as the risk of all-cause mortality (1.00 vs. 1.25 deaths per 100 person-life years) in the rosuvastatin-treated group.

k. The **Action to Control Cardiovascular Risk in Diabetes Lipid Trial (ACCORD Lipid) (2010)** was designed to evaluate whether the addition of fenofibrate to statin therapy among patients with type 2 diabetes would be effective in preventing cardiovascular events. The study randomized half of the patients within the initial ACCORD trial with type 2 diabetes and treated with a statin medication to fenofibrate (160 mg daily) or placebo. Although a significant reduction in triglyceride level (186 to 170 mg/dL) was seen with the addition of fenofibrate to statin therapy, there was no reduction in the primary end point (first occurrence of cardiovascular death, nonfatal MI, or nonfatal stroke) when compared with statin therapy alone.

In a subgroup analysis, a trend toward benefit of fenofibrate was shown in the group of patients with diabetes that had a significant dyslipidemia (low HDL and high triglycerides). Additional subgroup analysis showed a trend toward harm in women (but not men) in the fenofibrate group that warrants further investigation in future studies.

2. **Secondary prevention trials**
   a. The **Scandinavian Simvastatin Survival Study (4S) (1994)** was the first secondary prevention trial to demonstrate a clear reduction in total mortality. Simvastatin reduced total mortality among patients with CAD by 30%, largely because of a 42% reduction in deaths from CAD. The 4S treated 4,444 men and women with CAD and mean baseline LDL of 188 mg/dL, with a range of 130 to 266 mg/dL.
   b. The randomized, controlled **Cholesterol and Recurrent Events Trial (CARE) (1996)** was designed to evaluate the effects of treatment with pravastatin on 4,159 persons who had experienced acute MI 3 to 20 months before randomization and had moderately elevated TC levels (mean 209 mg/dL). The benefits of pravastatin therapy in preventing recurrent coronary events were similar in the subset analysis of age, sex, ejection fraction, hypertension, diabetes mellitus, and smoking.
   c. The **Long-Term Intervention with Pravastatin in Ischemic Disease Study (LIPID) (1998)** was the first to examine the use of a statin for patients with a history of unstable angina. The LIPID study provided new data on noncoronary mortality (i.e., stroke) and on other groups, such as women and patients with diabetes, who previously had been underrepresented in clinical trials. LIPID demonstrated improved CAD outcomes among all patients, including those with unstable angina.
   d. **The Veterans Affairs High-Density Lipoprotein Intervention Trial (VA-HIT) (1999)** was a multicenter study that randomized patients with known CHD and low high-density lipoprotein cholesterol (HDL-C) (≤ 40 mg/dL) and LDL-C (≤140 mg/dL) levels to gemfibrozil (1,200 mg/d) or placebo with a mean follow-up of 5.1 years. The study showed that gemfibrozil therapy was associated with a significant 22% reduction in the combined incidence of nonfatal MI and CHD death. This was the first lipid intervention trial to show that raising HDL-C concentrations in patients with CHD and low HDL-C and LDL-C levels will reduce the incidence of major coronary events.
   e. **Myocardial Ischemia Reduction with Acute Cholesterol Lowering Trial (MIRACL) (2001).** This trial demonstrated cardiovascular benefits with initiation of early statin therapy following acute coronary syndrome (ACS). The trial randomized 3,086 adults with unstable angina or non–Q-wave MI to high-dose atorvastatin (80 mg/d) or placebo between 24 and 96 hours after hospital admission. There was a reduction in the primary end point of nonfatal infarction, cardiac arrest with resuscitation, or recurrent symptomatic ischemia requiring hospitalization in the atorvastatin group (14.8% vs. 17.4%, RRR of 16%). The benefit was driven primarily by a 26% reduction in recurrent symptomatic ischemia. The trial did not show a mortality benefit (death, MI, or need for revascularization).
   f. **Pravastatin or Atorvastatin Evaluation and Infection Therapy–TIMI 22 (PROVE-IT–TIMI-22) (2004).** This trial was designed to determine whether intensive lipid-lowering therapy in patients with ACS reduced major coronary events and mortality more than "standard" lipid lowering. A total of 4,162 patients who had been hospitalized for ACS within the preceding 10 days were randomized to atorvastatin 80 mg/d or pravastatin 40 mg/d. After 2 years of follow-up, the composite end point (all-cause mortality, MI,

unstable angina, coronary revascularization, and stroke) was significantly reduced by 16% with atorvastatin compared with pravastatin. High-dose atorvastatin was well tolerated, with no cases of rhabdomyolysis. Of note, the LDL-C level attained on atorvastatin 80 mg/d was 33 mg/dL lower than on pravastatin with a mean of 62 mg/dL. These results suggested that the use of intensive lipid-lowering therapy to achieve very low LDL-C levels was of benefit in a group of patients at high risk for recurrent coronary events.

g. **A to Z Trial: Phase Z (2004)—Early Intensive vs. a Delayed Conservative Simvastatin Strategy in Patients with Acute Coronary Syndromes (2004).** This trial studied whether early initiation of high-dose statin therapy would lead to a reduction in long-term cardiac events compared with a more conservative, delayed low-dose statin strategy in high-risk patients with ACS. The trial enrolled a total of 4,497 patients with a recent ACS, TC level ≤250 mg/dL, and at least one additional risk factor who were randomized to either intensive statin therapy strategy (simvastatin 40 mg for 1 month, followed by 80 mg through 2 years) or a conservative strategy (placebo for 4 months followed by simvastatin 20 mg through 2 years). Although the study showed an early and sustained reduction in LDL in the aggressive strategy arm, it did not show a significant reduction in the primary composite end point of cardiovascular events (cardiovascular death, MI, readmission for ACS, and CVA) or death from any cause compared with a more conservative strategy. There were also more patients who developed creatine kinase (CK) concentrations more than 10 times the upper limit of normal in the aggressive strategy arm (9 vs. 1) and 3 patients who developed rhabdomyolysis while on simvastatin 80 mg.

h. The **Treating to New Targets (TNT) (2005)** trial sought to demonstrate the benefit of intensive lipid-lowering therapy in patients with stable coronary disease. The trial randomized 10,001 patients with clinically evident CHD and baseline LDL-C levels < 130 mg/dL to atorvastatin 80 mg/d or atorvastatin 10 mg/d. After 4.9 years of follow-up, the group receiving atorvastatin 80 mg/d had a 22% RRR in the primary composite end point of death from CHD, nonfatal MI, resuscitation after cardiac arrest, or fatal or nonfatal stroke compared with the group receiving atorvastatin 10 mg/d. High-dose atorvastatin was remarkably safe, with a 1.2% incidence in elevation of alanine aminotransferase (ALT)/aspartate aminotransferase (AST) more than three times the upper limit of normal, compared with a 0.2% incidence in the atorvastatin 10 mg group. Rates of myalgias and rhabdomyolysis were similar between the two groups. This study provided compelling evidence that the use of intensive statin therapy to reduce LDL-C to levels below 100 mg/dL had marked clinical benefit in patients with stable CHD.

i. The **Incremental Decrease in End Points through Aggressive Lipid Lowering (IDEAL) (2005)** trial randomized 8,888 patients with a prior history of acute MI to atorvastatin 80 mg/d or simvastatin 20 mg/d. After 4.8 years of follow-up, there was a nonsignificant difference in the risk of the composite end point of coronary death, acute MI, or cardiac arrest. However, if either stroke or revascularization was added to the primary end point, the results favored the atorvastatin group, and the associated hazard ratios were similar to the results of PROVE-IT and TNT. Despite the published negative result of this trial, it provided complementary evidence for the benefit of intensive LDL lowering in patients at high risk for coronary events.

j. The **Atherothrombosis Intervention in Metabolic syndrome with low HDL/high triglycerides: Impact on Global Health outcomes (AIM-HIGH) (2011)** was a study that compared treatment of extended-release niacin versus placebo among statin-treated patients with established heart and vascular disease. The study randomized 3,414 patients with

optimally treated LDL-C and low HDL-C with established vascular disease (documented by coronary angiography or by prior MI, or carotid angiography or prior ischemic stroke, or peripheral arterial disease) to extended-release niacin (1,500 to 2,000 mg/d) or placebo. There was no significant difference in the primary composite outcome of CHD death, nonfatal MI, ischemic stroke, hospitalization for ACS, or symptom-driven coronary/cerebral revascularization (16.4% in the extended-release niacin group vs. 16.2% in the placebo group). The study was terminated 18 months early after it was evident that the addition of extended-release niacin would not be beneficial. Furthermore, there was a small (numerical) excess in ischemic strokes and hospitalizations for ACS.

3. **Meta-analyses**
   a. **CTT Collaborators (*Lancet*, 2005).** A large meta-analysis of 90,056 individuals from 14 randomized trials of statin drugs, this analysis demonstrated an impressive 12% reduction in all-cause mortality for each 1 mmol/L (39 mg/dL) reduction in LDL. There was a 19% reduction in coronary mortality and 21% reduction in MI, coronary revascularization, and stroke. Statin use showed benefit within the first year of use, but was greater in subsequent years. Statins were also remarkably safe, with no increase in cancer seen and a 5-year excess risk of rhabdomyolysis of 0.1%.
   b. **Cannon—Intensive Statin Therapy (*J Am Coll Cardiol*, 2006).** A meta-analysis of 27,548 patients from four trials that investigated intensive versus standard lipid-lowering therapy found a significant 16% odds ratio reduction in coronary death or MI in the group that received intensive therapy. There was a nonsignificant trend toward decreased cardiovascular mortality.

C. Management of lipids. Despite overwhelming evidence supporting the treatment of dyslipidemia, a large number of patients remain untreated. The NCEP Adult Treatment Panel III (ATP III) has released guidelines for the treatment of hyperlipidemia in adults. These guidelines focus on identification of the risk of cardiovascular morbidity and appropriate targeting of therapy. The guidelines were last updated in 2004, with the next update planned for 2012.

1. **Guidelines for primary prevention of CAD events** based on the NCEP ATP III
   a. **TC, LDL-C, and HDL-C levels.** All adults 20 years or older and **without a history of CAD or other atherosclerotic disease** should have a fasting lipid panel (i.e., TC, LDL-C, HDL-C, and triglyceride levels) every 5 years. If a nonfasting lipid panel is obtained and the TC level is 200 mg/dL or the HDL-C is < 40 mg/dL, a follow-up fasting lipid panel is recommended (Table 43.2).
   b. **Determination of risk.** The patient's risk of future events is based on the presence of known CAD or clinical atherosclerosis in a noncoronary bed, diabetes mellitus (i.e., CAD equivalent), and other risk factors. These include age (men 45 years or older and women 55 years or older), smoking, hypertension (> 140/90 mm Hg or use of antihypertensive medication), family history of premature CAD (defined as CAD in first-degree male relatives before the age of 55 years and in a first-degree female relative before the age of 65 years), and low HDL-C (< 40 mg/dL). An **HDL-C level 60 mg/dL or greater is considered a negative risk factor**. Patients are classified into three categories of risk based on these factors.
      (1) **CHD risk.** Patients with highest risk of cardiovascular events are those with established CAD or evidence of atherosclerosis in noncoronary beds (i.e., abdominal aortic aneurysms, peripheral arterial disease, or symptomatic carotid disease), **diabetes mellitus**, or presence of multiple risk factors conferring a calculated 10-year risk of > 20%. The risk is calculated according to the Framingham risk score. The target LDL-C level for this group is < 100 mg/dL.

TABLE 43.2 Lipid Classification According to the National Cholesterol Education Program III

Risk factor	Goal
LDL-C	
< 100	Optimal
100–129	Near or above optimal
130–159	Borderline high
160–189	High
≥ 190	Very high
Total cholesterol	
< 200	Desirable
200–239	Borderline high
≥ 240	High
HDL-C	
< 40	Low
≥ 60	High

HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol.

(2) The second category includes patients with multiple risk factors and an estimated 10-year risk of adverse events between 10% and 20%. The target LDL-C level for this group is < 130 mg/dL.

(3) The third category includes those with no or one risk factor and an estimated 10-year risk of < 10%. The target LDL-C level in this group is < 160 mg/dL.

c. Treatment of dyslipidemia. The treatment of hyperlipidemia requires two approaches: therapeutic lifestyle changes (TLCs) and medications (Table 43.3). To achieve target LDL levels, most patients need both approaches simultaneously.

(1) CHD risk equivalent. These patients are at the highest risk of adverse events and, therefore, benefit the most from aggressive treatment. NCEP III, whose recommendations were published in 2001, had recommended therapy with a statin and TLCs if the LDL-C level was 130 mg/dL or greater. In patients with LDL-C levels between 100 and 130 mg/dL, it is suggested that the clinician use judgment as to whether to begin treatment with a statin, TLCs, or another agent such as niacin or a fibrate. **The 2004 update, however, was more definitive and recommended starting a statin and TLCs for all patients with a CHD risk equivalent with LDL-C levels 100 to 130 mg/dL.** This was based on cited evidence from the HPS and was further supported by the CARDS and ASCOT-LLA trials. In patients who have a baseline LDL-C concentration of < 100 mg/dL, the 2004 update stopped short of recommending initial use of a statin, but acknowledged that there was evidence for statin use in this group regardless of the LDL-C level. It did, however, state that initiation of a statin drug in patients with an initial LDL-C < 100 mg/dL who are

TABLE 43.3 Low-Density Lipoprotein Cholesterol Goals and Cutpoints for Therapeutic Lifestyle Changes and Drug Therapy in Different Risk Categories

Risk category	LDL goal (mg/dL)	LDL level at which to initiate TLC (mg/dL)	LDL level at which to consider drug therapy
CHD or CHD risk equivalent (10-y risk > 20%)	< 100	≥ 100	≥ 130 mg/dL (100–129 mg/dL: drug optional)
2+ risk factors (10-y risk ≤ 20%)	< 130	≥ 130	10-y risk 10–20%: ≥ 130 mg/dL 10-y risk < 10%: ≥ 160 mg/dL
0–1 risk factor	< 160	≥ 160	≥ 190 mg/dL (160–189 mg/dL: LDL-lowering drug optional)

CHD, coronary heart disease; LDL, low-density lipoprotein; TLC, therapeutic lifestyle changes.

at "very high risk" for future CVD events, with the goal of lowering the LDL-C to < 70 mg/dL, was a "reasonable therapeutic option." The cited evidence included the HPS and PROVE-IT–TIMI-22 trials. The publication of the TNT trial provided even more evidence for intensive lipid lowering in all patients with clinically evident CHD. **Given the balance of evidence in the most recently published trials and meta-analyses, a reasonable current approach for most clinicians would be to initiate statin therapy in all patients with CHD or a CHD risk equivalent, regardless of baseline LDL-C level, with a goal LDL-C of ≤ 70 mg/dL for patients with CHD or at high risk for future CVD events.**

(2) **Ten-year risk of 10% to 20%.** These are generally patients with two or more risk factors for CVD events. The target LDL-C level for this group is < 130 mg/dL. The 2004 ATP III update stated that an LDL-C goal < 100 mg/dL is a therapeutic option, and initiation of statin therapy along with TLCs for patients with baseline LDL-C level 100 to 130 mg/dL was reasonable. This recommendation was based on evidence from the HPS and ASCOT-LLA trials.

(3) **Ten-year risk < 10% and zero or one risk factor.** These patients should be treated with TLC to achieve a target LDL-C level < 160 mg/dL. If the LDL-C concentration remains above 160 mg/dL after 3 months of TLCs, drug therapy may be considered. Pharmacotherapy is recommended in those with LDL-C levels > 190 mg/dL. Factors favoring the use of drugs include a 10-year risk close to 10% or the presence of a severe risk factor such as a strong family history of premature CAD, a very low HDL level, poorly controlled hypertension, or heavy smoking.

2. **Types of therapy**

a. **TLCs** encompass **increased physical activity, ideal weight maintenance, and a diet** that includes a reduced intake of saturated fat (< 7% of total calories) and cholesterol (< 200 mg/d). Other TLCs are listed in Table 43.4. Intake of *trans*-fatty acids should be kept to a minimum. For most patients, it is essential to reduce saturated fat intake over total fat intake; for patients with metabolic syndrome, a fat intake of 30% to 35% may be optimal for reducing lipid and nonlipid risk factors. High-carbohydrate diets may worsen the lipid abnormalities in these patients. Dietary carbohydrates should be

TABLE 43.4 Components of Therapeutic Lifestyle

Component	Recommendation	Approximate LDL reduction
Diet		
Saturated fat	< 7% of total calories	8–10%
Dietary cholesterol	< 200 mg/d	3–5%
Polyunsaturated fat	Up to 10% of total calories	
Monounsaturated fat	Up to 20% of total calories	
Total fat	25–35% of total calories	
Carbohydrate	50–60% of total calories	
Dietary fiber	20–30 g/d	
Total protein	15% of total calories	
Therapeutic options for LDL lowering		
Plant stanols/sterols	2 g/d	6–15%
Increased viscous soluble fiber	5–10 g/d (consumption of 10–25 g/d may have added benefit)	3–5%
Physical activity	Enough moderate activity to expend at least 200 kcal/d	

LDL, low-density lipoprotein.

derived predominantly from foods rich in complex carbohydrates, such as whole grains, fruits, and vegetables. Daily intake of 5 to 10 g of viscous fiber reduces LDL levels by approximately 5% and the use of plant stanols and sterols (2 to 3 g/d) by another 6% to 15%. **TLCs can achieve an almost 30% reduction in LDL-C level in highly motivated individuals and should form the cornerstone of all preventive activity**. Benefits of LDL-C lowering may be evident within 6 to 12 months, although the individual response to a cholesterol-lowering diet depends on many factors. Some of the response is genetically determined, and increased body mass index is associated with less response to dietary change. LDL-C should be measured 6 weeks after initiating TLC diet, and if the goals are not met, intensification of TLCs and use of plant sterols or stanols should be considered. Referral to a dietitian for education and dietary counseling is often invaluable at this stage. If, after 3 months of TLCs, adequate control is not achieved, drug therapy should be considered.

b. Pharmacotherapy. The high efficacy of statins in lowering LDL-C level and their demonstrated mortality benefits make them the agents of first choice for treatment of most forms of hyperlipidemia. Table 43.5 summarizes the most commonly used agents affecting lipoprotein metabolism.

(1) HMG-CoA reductase inhibitors. The third report of the NCEP ATP included **HMG-CoA reductase inhibitors** among the first-line alternatives in the management of hypercholesterolemia. The category includes six drugs: lovastatin, simvastatin, pravastatin, fluvastatin, atorvastatin, and rosuvastatin.

TABLE 43.5 Drugs Affecting Lipoprotein Metabolism

Drug class	Agents and daily doses	Lipid/lipoprotein effects	Side effects	Contraindications
HMG-CoA reductase inhibitors (statins)	Lovastatin (20–80 mg) Pravastatin (20–40 mg) Simvastatin (20–80 mg) Fluvastatin (20–80 mg) Atorvastatin (10–80 mg) Rosuvastatin (10–40 mg)	LDL-C ↓ 18–55% HDL-C ↑ 5–15% TG ↓ 7–30%	Gastrointestinal distress Myopathy Increased liver enzymes	Absolute: – Active or chronic liver disease Relative: – Concomitant use of certain drugs[a]
Bile acid sequestrants	Cholestyramine (4–16 g) Colestipol (5–20 g) Colesevelam (2.6–3.8 g)	LDL-C ↓ 15–30% HDL-C ↑ 3–5% TG—no change or increase	Gastrointestinal distress Constipation Decreased absorption of other drugs	Absolute: – Dysbeta-lipoproteinemia – TG > 400 mg/dL Relative: – TG > 200 mg/dL
Nicotinic acid	Immediate release (crystalline nicotinic acid [1.5–3 g]) Extended release (Niaspan; 1–2 g) Sustained release (1–2 g)	LDL-C ↓ 5–25% HDL-C ↑ 15–35% TG ↓ 20–50%	Flushing Hyperglycemia Hyperuricemia (or gout) Upper GI distress Hepatotoxicity	Absolute: – Chronic liver disease – Severe gout Relative: – Diabetes – Hyperuricemia – Peptic ulcer disease
Fibric acids	Gemfibrozil (600 mg bid) Fenofibrate (200 mg) Clofibrate (1,000 mg bid)	LDL-C ↓ 5–20% (may be increased in patients with high TG) HDL-C ↑ 10–20% TG ↓ 20–50%	Dyspepsia Gallstones Myopathy	Absolute: – Severe renal disease – Severe hepatic disease

[a]Cyclosporine, macrolide antibiotics, various antifungal agents, and cytochrome P450 inhibitors (fibrates and niacin should be used with appropriate caution).

GI, gastrointestinal; HDL-C, high-density lipoprotein cholesterol; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL-C, low-density lipoprotein cholesterol; TG, triglyceride.

(a) Effectiveness. When dietary measures are inadequate, HMG-CoA reductase inhibitors effectively **lower TC and LDL-C levels in patients with mixed hyperlipidemias** (i.e., elevated cholesterol and triglyceride levels). HMG-CoA reductase inhibitors are **extremely effective in reducing LDL-C levels in most patients with primary hypercholesterolemia.** HMG-CoA reductase inhibitors decrease TC by 15% to 60% and LDL-C by 18% to 55% and increase HDL-C levels by 5% to 15%. Declines in apo B levels commensurate with reductions in LDL have been demonstrated. Statins also reduce triglyceride levels by 7% to 30% but have minimal effects on apo A1, apo A2, and lipoprotein (a) [Lp(a)]. **All statin drugs at the starting dose and within one to two dose titrations are well tolerated, efficacious**, and reasonably equivalent with respect to safety profiles.

(b) Adverse effects. Statins are remarkably safe drugs, with a low incidence of side effects. However, they are contraindicated in pregnancy.

(i) Minor side effects. The most common side effects are **mild gastrointestinal disturbances** (e.g., nausea, abdominal pain, diarrhea, constipation, and flatulence). Headache, fatigue, pruritus, and myalgias are other minor side effects, but none of these complaints usually warrant discontinuation of therapy.

(ii) Liver function test abnormalities. Mild, transient elevations in liver enzymes have been reported with all HMG-CoA reductase inhibitors. Marked elevation of transaminases is rare, but clinicians should avoid or use caution before starting statins in patients with acute or chronic liver disease. In the HPS, only 0.5% of patients had to stop treatment because of elevated ALT levels. Even when taking the highest dose of atorvastatin (80 mg), patients in PROVE-IT and TNT had only a 3.3% and 1.1% incidence, respectively, of transaminase elevation more than three times the upper limit of normal. In general, for each doubling of a statin dose, there is a 0.6% increase in risk of elevation of transaminase levels. **Current recommendations state that therapy should be discontinued when greater than threefold elevation occurs**. Enzyme levels typically return to normal within 2 weeks. Lower doses of the same medication can be reinstituted or a different statin can be tried. **Monitoring of hepatic aminotransferase levels is recommended for those taking HMG-CoA reductase inhibitors, but the frequency of monitoring has been debated**. Current package inserts for most statins recommend obtaining a liver panel prior to initiation of statin therapy, prior to dose titration, and when "clinically indicated." More frequent monitoring is recommended for patients taking the highest dose of a statin. In recent clinical trials, the high-dose statin that appears to have the highest incidence of transaminase elevation is atorvastatin. A panel of hepatologists who examined the potential hepatotoxicity of statins made a recommendation to obtain a liver panel prior to initiating statins as a baseline measurement of hepatic transaminases and bilirubin. If the baseline measurements were within normal limits, the panel recommended follow-up measurement of transaminases only if there was symptomatic or physical evidence of liver disease. An ACC/AHA/NHLBI clinical advisory panel on the safety and use of statins recommends measurement of transaminases at baseline, 12 weeks after starting therapy, and then annually or more frequently if indicated.

(iii) **Myopathy**, a rare but potentially serious side effect of HMG-CoA reductase inhibitors, presents with muscle pain, stiffness, or aching and elevations in serum CK level to more than 10 times the upper limit of normal. **CK measurements are not needed unless symptoms occur**. Statin-naïve patients should be warned to report symptoms of muscle pain or stiffness immediately if they occur after starting the drug. The risk of myopathy may be increased in the elderly, those with a low body mass index, those with multisystem disease such as chronic renal failure, those in the perioperative period, and those on multiple medications. Simvastatin 80 mg has been associated with a slightly higher incidence of myopathy and rhabdomyolysis compared with other statins, especially when combined with gemfibrozil. This could be due to the decreased rate of plasma clearance of simvastatin in older versus younger patients. Death from statin-induced rhabdomyolysis is exceedingly rare, with an incidence of 1.5 deaths per 10 million prescriptions. Statin-associated myalgias (muscle symptoms without elevations in serum CK) occur with somewhat higher frequency, about 1.4% to 1.5% in published clinical trials, and can appear at any time during statin therapy, even years after initiation of treatment. Muscle symptoms usually resolve with discontinuation of the statin. There is recent evidence that statin inhibition of mitochondrial coenzyme Q10 may be responsible for statin-induced myalgias, and there is evidence from small clinical trials that oral coenzyme Q10 supplementation may decrease symptoms of statin-associated myalgias.

(iv) **Drug interactions.** When statins are used in combination with certain pharmaceutical agents, such as erythromycin, gemfibrozil, azole antifungals, cimetidine, methotrexate, or cyclosporine, the risks of CK elevation and myositis increase. These drug combinations should be avoided or used judiciously with interval measurements of CK levels and liver function. Pravastatin and fluvastatin are safer in combination with other drugs because these two drugs do not use the cytochrome P450 3A4 microsomal pathways for metabolism. Verapamil and amiodarone are two commonly used cardiovascular agents that inhibit this pathway, and the concurrent use of simvastatin, atorvastatin, or lovastatin may, therefore, predispose to an increased risk of myositis. Recently, the US Food and Drug Administration (FDA) has recommended that simvastatin should not be prescribed at a dose of 80 mg, given the higher rate of myopathy at this dose unless patients have already safely taken this dose for > 12 months. Patients requiring this dose to maintain lipid goals should be transferred to another statin drug capable of achieving that goal. Simvastatin dosage in combination with amiodarone, diltiazem, or verapamil should not exceed 10 mg daily and should not exceed 20 mg daily in combination with amlodipine or ranolazine.

(2) **Bile acid sequestrants** lower LDL-C level by interfering with reabsorption of bile acids in the distal ileum, reducing the amount returned to the liver. They are safe and free of systemic side effects because they are not systemically absorbed; however, gastrointestinal side effects such as constipation are common, and compliance is poor as a result. The average LDL level decrease is approximately 15% to 30%, with a small rise seen in HDL level (3% to 5%). Triglycerides show no change or may

rise; therefore, these agents should be avoided in patients with elevated triglycerides. Two small angiographic trials, the NHLBI Type II Coronary Interventional Study and the St. Thomas Atherosclerosis Regression Study (STARS), have demonstrated reduced progression of CAD on serial angiograms in men with hypercholesterolemia who were taking cholestyramine. These agents may be of particular benefit in patients with minor elevation in LDL-C, for young patients, for women considering pregnancy, and in combination with a statin in those with very high LDL-C levels. In a pregnant patient, additional supplementation of iron and folate may be necessary because resins used over the long term can interfere with their absorption.

(3) **Nicotinic acid or niacin.** Niacin affects all lipid parameters favorably (i.e., LDL reduction of 5% to 25%, triglyceride reduction of 20% to 50%, and HDL elevation of 15% to 35%). It is one of the only agents that reduces Lp(a) significantly (up to 30%). Unfortunately, compliance is poor because of frequent side effects. Flushing and pruritus, gastrointestinal discomfort, glucose intolerance, and hyperuricemia often accompany the use of niacin. Hepatotoxicity is rare but is more commonly seen with the sustained-release preparation. It is often heralded by a dramatic reduction in lipid levels. There are limited data on long-term therapy with this agent. Niacin may be particularly useful for patients who do not have substantial elevations in their LDL-C levels, and low doses may be used to treat diabetic dyslipidemia. High doses should be avoided in patients with diabetes, and the drug should be avoided in those with a history of gout, peptic ulcer disease, or active hepatic disease.

(4) **Fibrates are effective at lowering triglyceride levels** by 20% to 50% and raising HDL levels by 10% to 20%. The mechanism of action involves activation of the nuclear transcription factor peroxisome proliferator–activated receptor alpha, with resultant increases in hepatic synthesis of apo A1 and A2 (raising HDL) and increase in lipoprotein lipase–mediated lipolysis, thus lowering triglyceride levels. LDL level reduction varies with the agent used and may range from 5% to 20% in patients who are not hypertriglyceridemic. Fenofibrate appears to lower LDL more effectively than gemfibrozil. Although a higher mortality rate was seen in the clofibrate arm of the World Health Organization (WHO) clofibrate study, such a finding was not seen in subsequent studies of gemfibrozil or fenofibrate. These agents have been demonstrated to impart a reduction in risk of CAD events and are of use in patients with elevated triglycerides. The VA-HIT (1999) found a reduction in fatal and nonfatal MI with gemfibrozil use in men with CAD who had low HDL levels (mean of 32 mg/dL), but the FIELD trial (2005) did not find a significant reduction in the primary end point of CAD death or MI in diabetic patients. Although fibrates are often used in combination with statin therapy to treat mixed dyslipidemia, there are no studies demonstrating reduction in clinical events with this approach. This combination increases the risk of myopathy. For patients with very high triglyceride levels (> 1000 mg/dL), fibrate therapy reduces the risk of pancreatitis.

(5) **Cholesterol absorption inhibitors** such as ezetimibe inhibit cholesterol absorption by the enterocyte. Ezetimibe reduces cholesterol absorption from the small bowel by 23% to 50% and reduces serum LDL level by 14% to 20% when used in combination with a statin. Reduction in clinical end points or surrogate end points has not been demonstrated for this group of drugs in all people. The SHARP trial (Study of Heart and Renal Protection) reported that cholesterol lowering with a combination

of simvastatin and ezetimibe in patients with chronic kidney disease significantly reduced the risk of major atherosclerotic events by 17%, including significant reductions in the risk of nonhemorrhagic stroke and revascularizations, when compared with placebo. However, the ENHANCE study failed to demonstrate any additional benefit of the use of ezetimibe added to statin over statin alone in slowing progression of carotid intimal thickness in a cohort of patients with familial hyperlipidemia. A number of large-scale studies are currently in progress seeking to determine the utility of a statin ezetimibe combination on hard cardiovascular end points. IMPROVE-IT, a phase III trial comparing ezetimibe/simvastatin versus simvastatin in subjects with stabilized high-risk ACS, is currently underway.

(6) **Cholesteryl ester transfer protein (CETP) inhibitors** such as torcetrapib, dalcetrapib, anacetrapib, and evacetrapib inhibit the process in which triglycerides from VLDL or LDL are exchanged for cholesteryl esters from HDL, resulting in higher HDL levels and reduction of LDL levels. Results from a torcetrapib study in 2004 demonstrated a significant increase in HDL (61%) and a decrease in LDL (17%) when receiving the drug in addition to atorvastatin and a 46% increase in HDL when receiving the drug alone. However, the phase 3 ILLUMINATE trial was terminated in 2006 after an increase of cardiovascular events and mortality was shown to be associated with the drug. Early results from the DEFINE trial (Determining the Efficacy and Tolerability of CETP Inhibition with Anacetrapib) have reported a decrease of LDL by 36% and increase of HDL by 138% without associated increased CVD death or events. This is a medium-sized safety trial with 2-year follow-up due to complete in December of 2012.

(a) **Choice of an agent and combination therapy.** The use of statin therapy for treatment of hyperlipidemia should be guided by the expected change in LDL-C levels (Table 43.6). Most statins have a log-linear dose–response pattern, with each doubling of dose associated with a further 7% reduction in LDL-C levels. Adverse effects of statins are also dose dependent and rise with the use of higher doses.

(i) **HMG-CoA reductase inhibitors and bile acid resins.** In isolated forms of LDL elevation, this combination exhibits highly complementary mechanisms of action. The combination of a statin with a bile acid sequestrant is ideal, owing to the lack of

TABLE 43.6 Average Reduction in Low-Density Lipoprotein Cholesterol Associated with the Starting Dose of Statin Agents

Agent	Average LDL-C reduction (%)
Lovastatin (20 mg)	24
Pravastatin (20 mg)	24
Simvastatin (20 mg)	35
Fluvastatin (20 mg)	18
Atorvastatin (10 mg)	37
Rosuvastatin (10 mg)	47

LDL-C, low-density lipoprotein cholesterol.

potentiation of side effects. The sequestrant provides little added toxicity, and the LDL-C lowering needed may not necessitate a full sequestrant dosage. Unfortunately, patient compliance with the combination is poor because of the common side effects of resins. Although the combination may reduce **LDL level by as much as 70% in some patients**, there appears to be a ceiling effect, with no LDL lowering occurring beyond the original level with an increase in dose of either agent.

(ii) **Combining a statin with niacin** is attractive because it can favorably influence all lipid subfractions. The side effects of the combination are increased but not synergistic, and the risk of myopathy may be lower than previously believed. The main serious side effect of the combination is hepatotoxicity, which may be reduced by using extended-release niacin. In small studies using this combination, the risk of hepatotoxicity (i.e., persistent elevation of AST or ALT of more than three times the upper limit of normal) at niacin doses of 2 g/d was about 1%.

(iii) The combination of a statin plus fibrate is highly effective for treating mixed hyperlipidemias. Although theoretically appealing, no reduction in clinical events has been demonstrated with this approach. The combination is associated with an increased risk of myopathy. Although earlier work suggested a higher incidence, later studies suggest this complication may be seen in approximately 1% of patients with the currently used agents.

(iv) The combination of a statin plus ezetimibe has been studied in small trials and has proved to be highly safe and effective at lowering LDL-C levels. Given the small number of patients treated and short follow-up periods, it is suggested that this combination should be reserved for the patients who fail maximal statin doses or are intolerant of statins.

3. Therapy of specific lipid disorders

a. Very high LDL levels usually result from inherited disorders of lipoprotein metabolism and carry a high risk of premature atherosclerosis with its attendant morbidity and mortality. **Hypothyroidism** may be associated with markedly elevated LDL levels and should be ruled out in any patient presenting with elevated LDL level. Most of these patients respond to high-dose statin therapy in addition to dietary restrictions. The addition of a bile acid sequestrant with an additional third agent (i.e., niacin) is often warranted to achieve target levels. Ezetimibe is another agent that may prove useful in this group. Therapy should be initiated early, and family members should be screened for hyperlipidemia. Patients with homozygous familial hyperlipidemia are deficient in LDL receptors, and measures that reduce cholesterol absorption (e.g., diet, ileal exclusion, bile acid sequestrants, and ezetimibe) or act by LDL receptor upregulation (e.g., statins) are largely ineffective. These patients are treated with LDL apheresis and should be managed in tertiary care centers only.

b. **Elevated triglyceride levels** may be caused by many factors, and more than one cause may be active in a given patient. **Minor elevations in triglyceride levels (150 to 299 mg/dL)** are usually caused by obesity, sedentary lifestyle, smoking, excess alcohol intake, and high-carbohydrate diets. In other patients, secondary causes such as diabetes, renal failure, Cushing's disease, nephrotic syndrome, or medications (e.g., protease inhibitors, corticosteroids, retinoids, and oral estrogens) may be responsible. Genetic causes may be pertinent to others. The therapy for this group of patients involves

identification and treatment of secondary causes (if present), change in medications, and lifestyle changes. These patients benefit from total caloric restriction and switching from a very high carbohydrate diet to a more balanced diet. Very high **triglyceride levels (≥500 mg/dL)** usually result from genetic defects of lipoprotein metabolism; in some patients, there is a combination of factors at play. These patients are at risk for acute pancreatitis (especially with triglyceride levels > 1,000 mg/dL), and treatment is directed at prevention of this condition. This is achieved with a combination of dietary measures (using very low fat diets [< 15% calories from fat] and substituting medium-chain fatty acids in patients with triglyceride levels > 1,000 mg/dL), increasing physical activity, maintaining optimal weight, and initiating fibrates or niacin therapy. Fibrates are especially efficacious in this group. Statins are not especially effective agents for triglyceride reduction and should be considered only after the other two agents. Patients with an **intermediate rise in triglyceride levels (200 to 499 mg/dL)** are a more heterogeneous group, with a wide array of underlying pathogenetic mechanisms at play. This pattern is often a result of an intersection of poor lifestyle, secondary causes, and genetic factors. These patients often have other markers of increased atherogenic risk, such as increased small LDL, low HDL, or elevated VLDL remnants. They need to be treated aggressively to bring the LDL level to the target; statins, with their ability to lower non-HDL-C, are the preferred agents. **After the LDL target has been achieved, the secondary goal is non–HDL-C (goal of 30 mg/dL higher than target LDL-C)**. These patients also need aggressive TLCs. High-dose statins often suffice to achieve the LDL-C and non–HDL-C goals, but for most patients, a second agent becomes necessary. The choices are niacin or fibrates in addition to a statin; these combinations carry an increased risk of hepatotoxicity or myopathy, and careful monitoring for these is essential. Refractory cases may benefit from fish oil supplements (> 3 g/d), which, by reducing VLDL production, can lower the serum triglyceride concentration by as much as 50% or more; however, many currently available over-the-counter fish oil supplements contain < 50% active omega-3 fatty acids. The commercial preparation Omacor, which has been available for many years in Europe and is now also available in the United States, contains 90% omega-3 fatty acids. The US FDA limited approval for Omacor to the treatment of severe hypertriglyceridemia (≥500 mg/dL) because of concerns that it appears to increase LDL-C levels. Weight loss by obese patients should be encouraged; it is associated with an improvement in the lipid profile and facilitates pharmacologic therapy if still necessary.

c. **Low HDL-C** levels often accompany minor or modest elevations in triglyceride levels. Low HDL level has been shown in epidemiologic studies to be an independent risk factor of CVD. However, despite a multitude of research on currently available therapies to raise HDL and recent investigation of several newer agents that raise HDL, there has been no conclusive evidence that raising serum HDL-C levels contributes to lower rates of CVD. Current guidelines specify that raising HDL should be a tertiary goal, after LDL and non–HDL-C goals have been reached. In patients who have isolated low HDL levels without any elevation in triglyceride levels, the first goal is to identify and modify lifestyle factors (e.g., high-carbohydrate diet, sedentary lifestyle, obesity, and smoking) and medications (e.g., progestational agents and anabolic steroids). The next step encompasses calculation of 10-year risk and treating LDL-C with a statin when appropriate. The AFCAPS/TexCAPS study found a clear benefit for statin therapy in patients with low HDL-C levels. In patients who continue to have low HDL-C levels despite

lifestyle modifications and who are at goal for LDL and triglycerides, either niacin or fibrate therapy is a reasonable choice to raise HDL-C.

d. Diabetic dyslipidemia. Patients with diabetes are at an increased risk for cardiovascular events and fare poorly after CAD manifests. Diabetes is associated with an increase in small LDL particles and is often associated with high triglyceride and low HDL levels. Hyperglycemia is an independent risk factor for CAD. Primary prevention is important in this group and was demonstrated to be efficacious in the HPS trial. **All diabetic patients (irrespective of LDL-C level) should be considered for statin therapy and TLCs**. Secondary goals include improved non–HDL-C levels and treatment for elevated triglyceride levels. Blood sugar control and insulin therapy often facilitate the former, but fibrates or low-dose niacin may be necessary in some patients. Patients with diabetes also often have coexisting hypertension. Blood pressure control and smoking cessation are essential because both interventions are highly effective at reducing cardiovascular events in this population.

CHAPTER 44

Clay A. Cauthen
Adam W. Grasso

Nonlipid Cardiovascular Risk Factors

I. INTRODUCTION. Dyslipidemia constitutes a strong and well-described risk factor for the development of coronary artery disease (CAD). Almost one-half of myocardial infarctions (MIs) in the United States occur in individuals without overt lipid abnormalities. Additional risk factors, including hypertension (HTN), diabetes, obesity, and lifestyle, must be addressed to reduce the incidence of cardiovascular events. This chapter describes these cardiovascular risk factors (except diabetes, which is discussed in Chapter 45). Novel biomarkers and risk factors are also discussed.

II. HYPERTENSION. HTN contributes to all cardiovascular comorbidities: CAD, MIs, cerebrovascular accident (CVA), systolic heart failure, diastolic heart failure, and peripheral vascular disease (PVD). It is associated with increased total mortality among men and women of all ages and ethnic groups, regardless of CAD. It is defined as a blood pressure of ≥ 140/90 mm Hg **or** the need for antihypertensive medication. It is thought to be present in at least 30% of the US adult population. Evidence from the Framingham Heart Study suggests that this is underestimated, as normotensive 55-year-old persons have a 90% residual lifetime risk of developing HTN.

A. Etiology. HTN is a complex disease modified by environmental and genetic determinants.

1. **Genetics. HTN does not follow the classic Mendelian rules of inheritance** attributable to a single gene locus.
   a. However, Liddle syndrome (mutation of **chimeric 11-β-hydroxylase–aldosterone synthase gene**) and variants in the angiotensinogen locus are documented exceptions that cause primary HTN among whites.
   b. Other potential candidate genes include various components of the **renin–angiotensin–aldosterone system, the kallikrein–kinin system, and the sympathetic nervous system**.
2. Increased left ventricular (LV) mass and LV wall thickness and altered peripheral vascular capacity and responsiveness occur more frequently among patients with a family history of HTN.
3. Contributors to HTN include variations in sodium intake, alcohol intake, renal function, vascular function, the sympathetic nervous system, the renin–angiotensin system, hyperinsulinemia/insulin resistance, and prostaglandins.

B. HTN impact on cardiovascular risk and mortality

1. **Positive relationship between systolic and diastolic blood pressures and cardiovascular risk** has long been recognized.
   a. The **Multiple Risk Factor Intervention Trial (MRFIT)**. Prospective study (11.6 years of average follow-up period) with more than 361,000 subjects demonstrated the relationship between blood pressure and CAD. Baseline blood pressure elevations increased risk for CAD. The relationship was

stronger for systolic blood pressure than for diastolic blood pressure. Death rate for men with systolic blood pressures of 140 to 149 (2.4/1,000) and 150 to 159 mm Hg (3.1/1,000) was 40% higher compared with men with a baseline systolic blood pressure < 120 mm Hg.

b. Death rate at follow-up can be lowered by 36% with primary prevention of HTN in the general population. In addition, rates of stroke and CAD fall with antihypertensive therapy.

c. Subjects with blood pressure < 120/< 80 mm Hg have the fewest cardiovascular events. The recommended treatment cutpoint is 140/90 mm Hg.

d. Prehypertension. This is defined as blood pressure within the high-normal range (120 to 139 mm Hg systolic or 80 to 89 mm Hg diastolic) and which may confer some increased risk for cardiovascular disease. Risk ratios of 2.5 for women and 1.6 for men have been reported in patients in the prehypertensive range. These patients should undertake lifestyle modifications (e.g., diet, exercise, and weight loss) to help prevent or delay the development of frank HTN in the future.

e. The gradual rise in blood pressure over a person's lifetime and the increased prevalence of **HTN among the elderly** are **not benign**. Epidemiologic studies of the elderly demonstrate a U-shaped relationship between blood pressure and mortality. After adjustment for deaths within the first 3 years of the follow-up period, there is a positive linear relationship between blood pressure, cardiovascular disease mortality, and all-cause mortality. Isolated systolic HTN increases as the population ages, which confers increased risk for morbidity and mortality.

(1) Systolic Hypertension in the Elderly Program (SHEP) showed that 8% of persons aged 60 to 69 years have isolated systolic HTN, defined as systolic blood pressure > 160 mm Hg and diastolic blood pressure < 90 mm Hg, as do 11% of those aged 70 to 79 years and 22% of those aged 80 years or older.

(2) The relationship between systolic and diastolic blood pressures and cardiovascular events is more pronounced among persons aged 65 years and older. The association is stronger and more consistent for systolic blood pressure than for diastolic blood pressure and is evident at levels considerably < 140 mm Hg.

2. Rate of cardiovascular events. Elevations in diastolic or systolic blood pressure values translate into significant increases in cardiovascular events. Generally, the yearly percent risk of cardiovascular events (i.e., risk of event by end of study, divided by duration of study) is between 0.5% and 2.5% for hypertensive subjects aged 40 years or older. Beginning at 115/75 mm Hg, each increase in blood pressure of 20/10 mm Hg doubles the risk of cardiovascular disease.

3. Systolic blood pressure is a greater predictor of risk. Over the last few years, **greater emphasis has been placed on systolic blood pressure in characterizing cardiovascular risk**. Age-adjusted 10-year mortality in the MRFIT revealed systolic blood pressure to be a stronger predictor of events from CAD than diastolic blood pressure. High systolic blood pressure conferred a CAD risk regardless of diastolic blood pressure. A systolic blood pressure of 140 to 149 mm Hg confers greater CAD mortality risk than a diastolic blood pressure of 90 to 94 mm Hg. A systolic blood pressure of 150 to 159 mm Hg carries greater risk than a diastolic blood pressure of 95 to 100 mm Hg. According to the SHEP study, isolated systolic HTN, which accounts for 60% of cases of HTN among the elderly, is highly correlated with cardiovascular disease and it is important that it is controlled.

C. Clinical presentation. Detection of HTN begins with proper **blood pressure measurements**, which should be obtained at each health-care encounter.

1. Data for evaluation are acquired through the medical history, physical examination, laboratory tests, and other diagnostic procedures. Evaluation of patients with documented HTN has the following three objectives:
   a. To identify known causes of high blood pressure
   b. To assess the presence or absence of end-organ damage and cardiovascular disease, the extent of the disease, and response to therapy
   c. To identify other cardiovascular risk factors or concomitant disorders that may define prognosis and guide treatment
2. A **medical history** should focus on identifying important risk factors or symptoms of HTN.
3. Repeated **blood pressure measurements** determine whether initial elevations persist and necessitate prompt attention, or the blood pressure has returned to normal and the patient needs only periodic surveillance. Ambulatory blood pressure monitoring is clinically helpful and is most commonly used to evaluate patients with suspected "office" or "white-coat HTN." It is also helpful in the care of patients with apparent drug resistance, hypotensive symptoms with antihypertensive medications, episodic HTN, and autonomic dysfunction.
   a. **Office visits.** Clinicians should explain to patients the meaning of their blood pressure readings and advise them of the **need for periodic remeasurement**. Blood pressure is measured in a standardized manner with equipment that meets certification criteria.
      (1) The patient sits in a chair with her or his back supported and the arms bared and supported at heart level.
      (2) Patients should refrain from smoking or ingesting caffeine during the 30 minutes preceding the measurement.
      (3) Measurement should begin after at least 5 minutes of rest.
      (4) The appropriate cuff size must be used to ensure accurate measurement. The bladder within the cuff should encircle at least 80% of the arm. Many adults need a large adult cuff.
      (5) Measurements are taken preferably with a mercury sphygmomanometer. Otherwise, a recently calibrated aneroid manometer or a validated electronic device can be used.
      (6) The systolic blood pressure and diastolic blood pressure are recorded. The first appearance of sound is used to define systolic blood pressure. The disappearance of sound is used to define diastolic blood pressure.
      (7) Two or more readings separated by 2 minutes should be averaged. If the first two readings differ by > 5 mm Hg, additional readings should be obtained and averaged.
   b. **Ambulatory blood pressure monitoring.** A variety of commercially available monitors that are reliable, convenient, easy to use, and accurate are available. These monitors are typically programmed to take readings every 15 to 30 minutes throughout the day and night while patients go about their normal daily activities. The readings can be downloaded for computer analysis.
      (1) **Normal** ambulatory blood pressure values are **lower than clinical readings while patients are awake** (< 135/< 85 mm Hg) and are **even lower while patients are asleep** (< 120/< 75 mm Hg). The blood pressure often falls by 10% to 20% during the night. This change is more closely related to patterns of sleep and wakefulness than to the time of day.
      (2) **Patients with HTN.** Ambulatory blood pressure correlates more closely than clinical blood pressure with a variety of measures of end-organ damage or left ventricular hypertrophy (LVH). Prospective evidence suggests that among patients for whom an elevated clinic pressure is the only abnormality, ambulatory monitoring may help identify a group at relatively low risk for morbidity.

4. **Physical examination** should include the following components:
   a. **Funduscopic examination** for hypertensive retinopathy (e.g., arteriolar narrowing, focal arteriolar constrictions, arteriovenous crossing changes, hemorrhages and exudates, and disk edema).
   b. Examination of the **neck** for carotid bruits, distended veins, or an enlarged thyroid gland.
   c. Examination of the **heart** for abnormalities in rate and rhythm, increased size, precordial heave, clicks, murmurs, and S_3 and S_4.
   d. Examination of the **lungs** for rales and bronchospasm.
   e. Examination of the **abdomen** for bruits, enlarged kidneys, masses, and abnormal aortic pulsation. Abdominal bruits, particularly those that lateralize to the renal area and/or have a diastolic component, suggest renovascular disease. Abdominal or flank masses may indicate polycystic kidneys.
   f. Examination of the **extremities** for diminished or absent peripheral arterial pulsations, bruits, hair loss, and edema. Delayed or absent femoral arterial pulses and decreased blood pressure in the lower extremities may indicate aortic coarctation.
   g. **Neurologic assessment.**
   h. **Other assessments.** Labile HTN or paroxysms of HTN accompanied by any or all of the following symptoms and signs—chest discomfort ("pressure"), headache ("pain"), palpitations, pallor, and diaphoresis ("perspiration")—may indicate the presence of a pheochromocytoma. Truncal obesity with purple striae suggests Cushing's syndrome.

D. Laboratory evaluation

1. It is recommended that the clinician request routine laboratory tests before initiating therapy to determine the presence of end-organ damage and other risk factors. These include **urinalysis, complete blood cell count, blood chemistry, and 12-lead electrocardiogram (ECG)**.
2. Additional diagnostic procedures may be indicated to seek causes of HTN: poor response to drug therapy, well-controlled patients whose blood pressures begin to increase, and those with sudden onset of HTN. **Optional tests** include creatinine clearance; microalbuminuria, 24-hour urinary protein, blood calcium, uric acid, fasting triglyceride, low-density-lipoprotein cholesterol (LDL-C), glycosylated hemoglobin, and thyroid-stimulating hormone levels; and limited echocardiography to determine the presence of LVH.
   a. **Clues from laboratory tests** include unprovoked hypokalemia (i.e., primary aldosteronism), hypercalcemia (i.e., hyperparathyroidism), and elevated creatinine or abnormal urinalysis (i.e., renal parenchymal disease).
   b. The **presence of LVH** as determined by ECG or echocardiography is an important risk factor for adverse cardiovascular events and an independent predictor of high risk for CAD, cardiovascular disease, and all-cause mortality. LVH, the consequence of chronic pressure or volume overload and obesity, seems to be a stronger predictor of MI and CAD death than the degree of HTN. LV mass, as assessed with echocardiography, is a powerful predictor of cardiovascular events, cardiovascular mortality, and all-cause mortality.
3. **More complete assessment** of cardiac anatomy and function by means of conventional echocardiography, examination of structural alterations in arteries by means of ultrasonography, measurement of ankle–arm index, and plasma renin activity and urinary sodium determinations may be useful in assessing **cardiovascular status** in select patients.

E. Risk stratification

1. **Classification of blood pressure** is given in Table 44.1. The criteria are limited to patients not taking antihypertensive medication and without acute illness. Classification is based on the average of two or more blood pressure readings. When systolic blood pressure and diastolic blood pressure fall into different categories, **the higher pressure should be selected** to classify the patient's blood pressure.

TABLE 44.1. Classification of Blood Pressure for Adults Aged 18 Years and Older

Category	Systolic blood pressure (mm Hg)		Diastolic blood pressure (mm Hg)
Normal	< 120	and	< 80
Prehypertension	120–139	or	80–89
Stage 1 hypertension	140–159	or	90–99
Stage 2 hypertension	≥ 160	or	≥ 100

2. Risk for cardiovascular disease among patients with HTN is determined by the **blood pressure level** and by the **presence or absence of end-organ damage or other disease-modifying risk factors** (smoking, dyslipidemia, and diabetes). The presence or absence of these factors is determined during the routine evaluation of patients with HTN (e.g., history, physical examination, and laboratory tests). This classification stratifies patients with HTN into risk groups for therapeutic decisions. The World Health Organization Expert Committee on Hypertension Control recommends a similar approach. Obesity and physical inactivity are also predictors of cardiovascular risk and interact with other risk factors, but they are of less importance in the selection of antihypertensive drugs.
   a. **Risk group A** includes patients with prehypertension or HTN at stage 1 or 2 who do not have clinical cardiovascular disease, end-organ damage, or other risk factors. Persons with stage 1 HTN in risk group A are candidates for a longer trial (up to 1 year) of vigorous lifestyle modification with vigilant blood pressure monitoring. If the desired blood pressure is not achieved, pharmacologic therapy is added. For those with stage 2 HTN, drug therapy is warranted.
   b. **Risk group B** includes patients with HTN who do not have clinical cardiovascular disease or end-organ damage but have one or more of the risk factors except for diabetes mellitus. This group includes most patients with high blood pressure. If multiple risk factors are present, clinicians consider antihypertensive drugs as initial therapy. Lifestyle modification and management of reversible risk factors are strongly recommended.
   c. **Risk group C** includes patients with HTN and clinically manifested cardiovascular disease or end-organ damage. According to Joint National Committee 7 (JNC 7) criteria, some patients who fall into the prehypertensive category and have renal insufficiency or diabetes mellitus should be considered for prompt pharmacologic therapy. Appropriate lifestyle modifications are always recommended as adjunct treatment.
   d. **Therapy.** Antihypertensive treatment has proved **beneficial in the prevention and reduction of the progression of HTN, CVAs, congestive heart failure (CHF), renal insufficiency, and renal failure**. Among patients with mild to moderate HTN, antihypertensive therapy has not favorably influenced angina, MI, and other atherosclerotic diseases (e.g., PVD and aortic atherosclerosis). The lower-than-expected reduction in CAD risk in most trials of antihypertensive agents has been attributed to the choice of agents, such as thiazide diuretics and β-blockers, that might negatively influence risk for CAD and to the short duration of the trials. Overall, antihypertensive treatment markedly reduces the prevalence of CAD events: CAD mortality (by 16%), the rate of fatal stroke (by 40%), and the incidence of heart failure (by 50%), with similar numbers of deaths prevented.

1. **Nonpharmacologic therapy**
   a. **Weight reduction** reduces systolic and diastolic blood pressures. Most clinical trials have demonstrated that weight reduction is directly related to blood pressure reduction. A weight loss of approximately 10 lb (4.5 kg) may reduce both systolic and diastolic blood pressures by 2 to 3 mm Hg. Among patients with high-normal blood pressure, the need for medical therapy may be averted for one-half through weight reduction by means of physical activity and calorie restriction.
   b. **Exercise** reduces blood pressure by means of decreasing resting heart rate and peripheral vascular resistance and by modifying serum norepinephrine and insulin levels. After an increase in physical activity, both systolic and diastolic blood pressures have been demonstrated to fall by 7 mm Hg with or without weight reduction. Moderate-intensity exercise is as effective as high-intensity exercise for reducing blood pressure.
   c. **Diet.** A modest, independent benefit of **salt reduction** has been demonstrated. HTN is less common in societies that consume low-salt, high-potassium diets. Although the theory that excessive salt intake produces HTN has been difficult to prove in large clinical trials, most data support the role of dietary salt excess for some persons. In general, low-salt diets, such as the Dietary Approaches to Stop Hypertension (DASH; 2,300- and 1,500-mg sodium diets), are recommended to most patients with HTN. Pooled estimates have suggested that **salt restriction is most important for older persons, those with higher baseline levels of blood pressure, and particularly those who are salt sensitive**. Salt restriction reduces the need for combination antihypertensive medications.
   d. Tobacco and immoderate alcohol use (more than two daily drinks for men and more than one daily drink for women) increase blood pressure. **Cessation of smoking and excessive alcohol use** markedly reduces blood pressure and further reduces cardiovascular risk.
2. **Medical therapy**
   a. **Priority of therapy**
      (1) Therapy for most patients with **uncomplicated HTN** at stage 1 should **begin with the lowest dose** to prevent adverse effects. If blood pressure remains uncontrolled after 1 to 2 months, the next dose level may be prescribed. It may take months to adequately control HTN. Most antihypertensive agents may be taken once each day. To improve patient compliance, this regimen is used whenever possible.
      (2) For patients at **higher risk**, those in risk group 2, or those at particularly high risk for CAD or CVA event, drug therapy to **achieve maximum beneficial reductions** in blood pressure should **proceed without delay.** If blood pressure is elevated by 20/10 mm Hg above the goal, guidelines recommend starting two agents simultaneously.
      (3) There is **no debate regarding the need for aggressive blood pressure reduction** in patients with **diastolic blood pressures > 115 mm Hg and systolic blood pressures > 160 mm Hg**. JNC 7 aggressively targets the 140/90 mm Hg cut-point and incorporates hypertensive therapy into an algorithm of overall risk.
      (4) In the setting of hypertensive emergency **(HTN with end-organ damage, often with neurologic symptoms)**, patients with a systolic blood pressure > 200 mm Hg or a diastolic blood pressure > 120 mm Hg may need **hospitalization** for therapy.
      (5) Although some patients may respond to single therapy, **two or more drugs are often required**. The intervals between changes in regimen should not be prolonged, and the maximum dose of some drugs may be increased.

b. Medication selection. Special considerations include concomitant disease, demographic characteristics, quality of life, cost, and use of other drugs that may cause drug interactions.

(1) Concomitant diseases (see Table 44.2). Antihypertensive medications may worsen some diseases and improve others. Agent selection involves consideration of coexisting disease, simplification of regimens, and reduction of cost. Special emphasis should be given to diabetes and chronic renal disease. Such patients should be aggressively treated to maintain a goal blood pressure of < 130/80 mm Hg.

(a) Reduction of long-term cardiovascular morbidity and mortality. Diuretics and β-blockers were drug classes originally shown in randomized trials to reduce morbidity and mortality. The Heart Outcomes Prevention Evaluation (HOPE) trial demonstrated that angiotensin-converting

TABLE 44.2. Management of Hypertension in Specific Clinical Syndromes

Condition	Treatment
Acute coronary syndrome	β-Blockers or nitrates; CCB
Hypertension among African Americans	Diuretic or CCB
Arrhythmia	
Sinus bradycardia, SSS, or AV block	Diuretic, ACE inhibitor, or α-blocker
Atrial fibrillation or flutter and SVT	β-Blocker, diltiazem, verapamil, or clonidine
Benign prostatic hypertrophy	α-Blocker
COPD with bronchospasm or asthma	CCB or ACE inhibitor
Diabetes	ACE inhibitor
Advanced age (> 65 y)	Diuretic, CCB, or ACE inhibitor at lower doses to avoid postural hypotension
Gout	Any *except* diuretics
Congestive heart failure	
Systolic	ACE inhibitor, diuretic, β-blockers
Diastolic	CCB or β-blockers
HOCM	β-Blockers or verapamil
Liver dysfunction	Any *except* methyldopa and labetalol
Post–myocardial infarction	ACE inhibitor, β-blocker, or both
Osteoporosis	Thiazide diuretics
PVD	Vasodilator, ACE inhibitor, CCB, or α-blocker
Renal insufficiency (creatinine > 2 mg/dL)	Loop diuretics, ACE inhibitor, CCB, α-blocker, labetalol, or a combination of these
Diabetic nephropathy	ACE inhibitor
Smokers	α-Blockers, ACE inhibitors, or CCB
Isolated systolic hypertension	Diuretics, CCB, and ACE inhibitors

ACE, angiotensin-converting enzyme; AV, atrioventricular; CCB, calcium channel blocker; COPD, chronic obstructive pulmonary disease; HOCM, hypertrophic obstructive cardiomyopathy; PVD, peripheral vascular disease; SSS, sick sinus syndrome; SVT, supraventricular tachycardia.

enzyme (ACE) inhibitors reduced the risk of cardiovascular events in patients with vascular disease or diabetes plus one other cardiovascular risk factor. However, the fact that HOPE was a trial with placebo control rather than active control suggests that blood pressure lowering, and not drug class effect, may have been responsible for the improved outcomes. The Losartan Intervention for Endpoint Reduction in Hypertension (LIFE) study showed a preferential reduction in cardiovascular events with the angiotensin receptor blocker losartan compared with atenolol in hypertensive patients. This improvement was primarily driven by a reduction in the number of strokes in the losartan group.

(b) Regression of LVH has been associated with a reduction in risk for cardiovascular events. All commonly used antihypertensive strategies, with the exceptions of direct vasodilators and weight loss, induce regression of LVH. Specifically, the ACE inhibitor ramipril has been shown to cause regression of electrocardiographic markers of LVH, with an associated reduction in death, MI, stroke, and CHF. The LIFE trial demonstrated a superiority of the angiotensin II receptor blocker losartan over the β-blocker atenolol in the absence of LVH regression, suggesting that LVH might not be as powerful a surrogate of risk as initially thought. Further study of this issue is needed.

(2) Dosage. For most patients, a **low dose of the initial drug** choice is initiated and then titrated to the desired effect. The optimal formulation provides 24-hour efficacy with a once-daily dose, with at least a 50% of the peak effect remaining at the end of 24 hours. Long-acting formulations increase adherence, reduce cost, provide consistent blood pressure control, and protect against early-morning sudden death. Diurnal blood pressure control is reported to improve when long-acting medication is taken at night rather than in the morning.

(3) Special populations. Neither sex nor age usually affects responsiveness to various agents. In general, HTN among **African Americans** is more responsive to monotherapy with diuretics and calcium channel blockers than with β-blockers or ACE inhibitors. However, if a β-blocker is needed for other therapeutic benefits, then differences in efficacy can usually be overcome with reduction of salt intake, higher doses of the drug, or addition of a diuretic.

(4) Drug interactions. Some drug interactions may be beneficial. For example, diuretics acting on different sites in the nephron may increase natriuresis and diuresis. Diltiazem may reduce the amount of cyclosporine needed in transplant recipients. Other interactions may be harmful. Nonsteroidal anti-inflammatory drugs may blunt the action of diuretics, β-blockers, and ACE inhibitors.

c. Treatment of the elderly. The benefit of blood pressure lowering is evident in the elderly, with a marked **reduction in all-cause mortality and CAD mortality**, as shown in multiple trials and studies. SHEP was the first study to show that antihypertensive treatment of the elderly can reduce these events. It is not clear, however, that all agents are equally effective in reducing the rate of cardiovascular events in the elderly.

d. Emerging evidence. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) compared the incidence of cardiovascular events in hypertensive patients treated with a thiazide-type diuretic (chlorthalidone), calcium channel blocker (amlodipine), or ACE inhibitor (lisinopril) who were followed over 5 years. A fourth arm of the trial consisting of treatment with the α-blocker doxazosin had been stopped prematurely because of increased cardiovascular events, specifically a doubling in the risk

of CHF in the doxazosin arm compared with the chlorthalidone arm. The results indicated no difference in the three remaining groups regarding the primary outcome of combined fatal coronary heart disease or nonfatal MI. Chlorthalidone was superior to amlodipine in preventing heart failure and superior to lisinopril in preventing stroke and combined cardiovascular disease. Given their clear efficacy, relatively low cost, and high tolerability, thiazide diuretics are therefore considered initial agents of choice for most patients with HTN and core components of multidrug regimens.

III. OBESITY. Rates of obesity are rising at an alarming rate both in the severe obesity cases (body mass index [BMI] > 40 kg/m^2) and in adolescents. Currently, 66% of US adults are overweight, defined as having a BMI of > 25 kg/m^2. Moreover, 32% of Americans are classified as obese, with a BMI of 30 kg/m^2 or more. This has come to be a critical problem for African American women, among whom the prevalence of obesity is > 50%. The percentage of children and adolescents with obesity has doubled over the last 20 years. There are clear links between obesity and the development of cardiac risk factors: HTN, hyperlipidemia, and diabetes.

A. Link between obesity and cardiovascular disease

1. A positive association among BMI, increased total cholesterol and triglyceride levels, and a decreased high-density-lipoprotein cholesterol (HDL-C) levels has been documented in various age groups.
2. Distribution of fat appears to be a more important predictor of CAD than the total amount of fat because android fat patterns are more metabolically active and highly associated with dyslipidemia. Although BMI and waist-to-hip ratios have indicated a linear association between obesity and CAD, the **waist-to-hip ratio**, which accounts for abdominal adiposity, is viewed as a more **accurate predictor of CAD**. Among obese persons, those with central adiposity are at particularly high risk. In a cohort of 1,500 women observed for 20 years, the waist-to-hip ratio, but not BMI, was highly predictive of the occurrence of fatal MI.
3. The **National Center for Health Statistics still uses BMI**, defined as **weight (kg)/height (m^2), as the recognized measurement of obesity**. Their guidelines define obesity as a BMI of 27.8 kg/m^2 or more for men and 27.3 kg/m^2 or more for women. Morbid obesity has been defined as a BMI of 31.1 kg/m^2 for men and 32.3 kg/m^2 for women. The Nurses' Health Study showed that women with a BMI of 25 to 29 kg/m^2 had an age-adjusted relative risk for CAD of 1.8 compared with the leanest women. Women with a BMI > 29 kg/m^2 had a relative risk for CAD of 3.3.
4. Obesity among adults is associated with **increased LV mass,** a powerful independent predictor of mortality and morbidity from cardiovascular disease. LV mass in persons with obesity but without diabetes probably depends, at least in part, on the degree of insulin resistance and hyperinsulinemia and not on BMI and blood pressure.
5. Central obesity is part of the **metabolic syndrome**, which appears to be associated with increased risk for CAD in both sexes. This condition is characterized by elevated plasma triglyceride and low plasma HDL-C levels.
   a. An essential feature is the presence of **dense, atherogenic LDL**.
   b. Other features are HTN, impaired glucose intolerance with hyperinsulinemia, and decreased sensitivity to the action of insulin on peripheral tissues.
   c. Hyperinsulinemia is associated with **lipid derangements, increased production of plasminogen activator inhibitor, and enhanced proliferation of cells in atherosclerotic plaque**. Among patients with hyperinsulinemia, an increased prevalence of CAD and a relationship among abnormal insulin levels, glucose metabolism, and severity of CAD have been reported. The physiologic response to insulin resistance is increased secretion of insulin, which may lead to glucose intolerance or frank diabetes mellitus.

B. Therapy

1. **Calorie restriction, behavior modification, and exercise** are the main treatment modalities for weight loss. The greatest weight losses have occurred with a combined regimen of diet and exercise rather than diet or exercise alone.
2. Several **medications** can be used for the temporary management of obesity. Although pharmacologic agents temporarily aid in the struggle against obesity, the National Task Force on Obesity **cautions against the use of these agents for long-term maintenance because of the potential for unknown side effects**.
   a. **Noradrenergic drugs** influence weight loss through stimulation of the hypothalamus.
   b. **Orlistat,** a pancreatic lipase inhibitor, reduces weight through inhibition of fat absorption.
   c. **Serotonin reuptake inhibitors**, including sibutramine, fluoxetine, and sertraline, promote weight loss with various degrees of side effects.
   d. Use of dexfenfluramine and fenfluramine, already of concern because of rare instances of pulmonary HTN, has been discontinued because of associated acquired valvular heart disease.
3. In the most extreme cases, **surgical therapy** can be provided. Among morbidly obese patients (BMI > 40 kg/m^2) and obese patients (BMI between 35 and 40 kg/m^2) with coexisting conditions, jejunoileal shunts and gastroplasty often aid in the maintenance of weight loss. About 10 years after surgical intervention, 80% of patients maintain a weight 10% less than preoperative weight.
4. **Risk of weight loss.** Even if weight is lost, weight loss maintenance fails in most instances. Health risks that accompany weight cycling are increases in cardiovascular morbidity and mortality, abdominal fat, blood pressure, and insulin resistance.

IV. TOBACCO. Smoking, the single most preventable cause of death in the United States, is a leading risk factor for CAD, CVA, and PVD. Second-hand smoke has been shown to increase the risk for CAD. The causal role of smoking in cardiovascular disease has been derived from > 20 million person-years of follow-up study (NHLBI, 1996). Twenty-eight percent of white men and 25% of white women smoke, as do 34% of African American men, 22% of African American women, 24% of Hispanic men, and 15% of Hispanic women. It is estimated that 37% of the population is exposed to second-hand smoke. Exposure to second-hand smoke increases the risk of death from CAD by 30%. More than 90% of current smokers began their habit before they were 21 years of age.

A. Pathophysiology. Cigarette use activates platelets, increases circulating fibrinogen, increases heart rate, and elevates blood pressure. It appears to promote plaque disruption. A strong dose–response relationship exists between smoking and CAD. Duration of smoking and the daily amount markedly influence the risk of CAD. The number of cigarettes smoked per day is directly proportional to the risk of MI. The adverse effect of smoking is present among men and women (but may be stronger among women) of all ages and ethnic groups with or without prior CAD. Data suggest that risk for cardiac death is two to four times greater among current smokers than nonsmokers.

B. Risk reduction and therapy. Risk for cardiovascular disease begins to decline soon after smoking cessation, irrespective of age and sex. There is a 50% reduction in cardiovascular events within the first 2 to 4 years of cigarette cessation; however, increased cardiovascular risk still exists 10 years after cessation. It is thought to take as long as 20 years to regain baseline risk.

1. **Behavioral and psychosocial treatment.** Several techniques have been developed to help patients stop smoking and maintain cessation. These have variable effect.
2. **Pharmacotherapy**
   a. **Nicotine replacement therapy (NRT).** Approximately 50% to 70% of patients discontinue cigarette use after a major cardiac event, such as MI or coronary artery bypass grafting. Cessation for another 10% to 20% can be accomplished with cigarette cessation programs, which often incorporate

nicotine patches or the somewhat less efficacious nicotine gum. Programs that incorporate a nurse clinician increase cessation rate beyond 30%. An 8-week treatment appears to be as effective as longer periods of use.

(1) **The patch.** Clinical practice guidelines support the use of transdermal nicotine patch as the **primary pharmacologic agent for all patients who smoke**. The risk of use of the patch among patients with CAD is now considered to have been overstated. Use of the patch is contraindicated in persons who continue to smoke because it leads to nausea. **Side effects** of NRT include itching and skin rash among as many as 50% of patients. NRT approximately doubles cessation rate. One-year follow-up evaluations of patch-cessation therapy indicated cessation rates of 20% to 25% compared with 5% to 10% for a placebo.

(a) Standard dosages (Nicoderm, Prostep, and Nicotrol) include the maximum doses for 4 weeks and lesser doses for another 4 weeks.

(b) Because baseline nicotine levels (i.e., the number of cigarettes smoked per day) are inversely associated with cessation rates, **patients who smoke < 1 pack per day** may be adequately treated with **submaximal nicotine doses**.

(2) **Nicotine gum.** Use of gum for NRT appears to delay post-cessation weight gain, a typical deterrent to cigarette cessation. Multipack users should use 4 mg gum, whereas patients who smoke < 1 pack per day may need only 2 mg.

(3) **Nicotine nasal spray** has been approved as a smoking cessation treatment. Nasal spray provides a more rapid rise in nicotine level than that with gum or patch, with peak levels occurring in < 10 minutes. Nicotine nasal spray has markedly more severe **side effects** and appears to be best suited for patients who have not had success with other forms of NRT.

b. **Other pharmacologic agents.** For select patients, supplementation with agents other than NRT may be useful, even though NRT is the only strategy recommended in standard smoking cessation guidelines.

(1) **Bupropion,** which is approved for smoking cessation, has dopaminergic and noradrenergic properties. Clinical trials have demonstrated the efficacy of bupropion sustained release (SR) with or without transdermal nicotine for smoking cessation. The recommended dosage of bupropion is 150 mg two times per day. In clinical trials, the medication was typically started 1 to 2 weeks before cessation and was continued for 7 to 12 weeks after cessation. Abstinence rates at 12 months were 30% for patients treated with bupropion for 9 weeks in one study, and combination therapy with bupropion and a nicotine patch resulted in a 35.5% abstinence rate.

(2) Bupropion must be **avoided by patients with a seizure disorder or who are at risk for seizures** (i.e., patients with head injury, those who abuse alcohol, or those who have alcohol dependence) because the medication lowers seizure threshold. Common **side effects** of bupropion include headache, nausea, and restlessness. Bupropion has no serious adverse effects on the cardiovascular system.

(3) **Clonidine**, an α_2-agonist, **dampens the sympathetic activity associated with withdrawal**. Dosages used for smoking cessation typically range from 0.1 to 0.4 mg/d for 2 to 6 weeks in the oral or the transdermal preparation. The most common **side effects** are dry mouth, constipation, postural hypotension, and sedation. Clonidine is **recommended for patients who prefer not to take or who have not had success with NRT**. Nasal spray clonidine has been effective among nicotine-dependent women who are intolerant of the patch.

(4) **Varenicline** is a partial agonist of the nicotinic acetylcholine receptor, in particular, the $\alpha_{4\beta2}$ subtype. Several trials have demonstrated improved

efficacy in achieving smoking cessation when compared with NRT and bupropion SR. However, because of case reports of adverse psychiatric behavior occurring during varenicline administration, including suicidal ideation, suicidal behavior, and erratic behavior, practitioners are encouraged to monitor their patients closely for signs of psychiatric changes.

V. SEDENTARY LIFESTYLE

A. Pathophysiology. A sedentary lifestyle is associated with increased risk for CAD. Sedentary persons have almost double the risk for CAD death as that of active persons. In five prospective exercise studies, persons at the lowest levels of exercise conditioning had an age-adjusted CAD mortality risk 2 to 10 times that of the best-conditioned participants. Meta-analyses of epidemiologic studies suggest a nearly twofold increase in risk among sedentary persons for development of CAD and for CAD death. A sedentary lifestyle is also associated with obesity, HTN, diabetes mellitus type 2, and hypercholesterolemia, which point to the need for changes in exercise patterns. More than 50% of the US population do not exercise at least 20 minutes three times a week and 40% of adults are classified as sedentary. Only 22% of US adults partake in 30 or more minutes of exercise five times a week and 25% report no leisure-time physical activity.

B. Risk reduction. Even moderate physical activity provides a reduction in risk. Regular physical activity prevents obesity, may reduce weight, and promotes positive effects on blood pressure, LDL-C, HDL-C, and triglyceride levels. Independent of other risk factors, physical fitness has a direct protective effect against CAD events. Among patients who have had MI, controlled cardiac rehabilitation programs significantly reduce cardiovascular mortality by 20% to 25%. The American Heart Association (AHA) currently recommends that adults accumulate 30 minutes or more of moderate-intensity physical activity on most (preferably all) days of the week.

1. **Mechanism**
   - **a.** Exercise **improves glucose tolerance and insulin sensitivity, increases fibrinolysis, increases HDL-C levels, improves oxygen uptake** in the heart, and **increases coronary artery diameter**. Exercise reduces the sensitivity of the myocardium to catecholamines and the risk of ventricular arrhythmias. Exercise increases HDL-C and lowers LDL-C levels and, as such, reduces cardiac events. Exercise can alter the progression of coronary atherosclerosis. Among patients with angiographically documented CAD, exercise training may increase regression and reduce the progression of coronary lesions.
   - **b.** Studies on the effect of exercise have been difficult to conduct and are known to have difficulties in quantification of exercise. Reviews on the effects of cardiac rehabilitation on morbidity and mortality demonstrated reductions in all-cause mortality of 20% to 24% and in CAD mortality of 23% to 25%. The data support a reduction in anginal episodes and mortality, although the reduction in mortality is no better than 15%. A direct relationship has been shown between exercise intensity and angiographic modifications: 1,533 kcal/wk is necessary to stabilize coronary lesions and 2,200 kcal/wk is needed to induce coronary regression.
2. **Fitness** (measured in metabolic equivalents or METs achieved) and **physical activity** (measured in caloric expenditure per time period) appear to be closely linked, although it remains unclear which of the two is the better predictor of cardiovascular morbidity and mortality.
   - **a.** Several studies have shown that **higher degrees of physical activity** are associated with decreased risk for death from CAD. There is an inverse association between the increasing physical activity (measured in MET-hours/week) and the risk of cardiovascular events. These studies suggest that **changes in fitness from low to high levels and level of current activity are the best predictors of reduction in risk for CAD**.

b. **The death rate decreased by 50% among men** 60 years or older who changed from unfit to fit status over an 18-year follow-up period. The age-adjusted cardiovascular disease mortality rate decreased by 52%.

c. An important measurement of fitness among **older postmenopausal women** is leisure-time physical activity; it can substantially reduce the risk of MI. Even moderate-intensity exercise has been shown to confer substantial benefits for postmenopausal women. Such women who walk or exercise vigorously at least 2.5 hours each week have been shown to have a cardiovascular risk reduction of approximately 30%.

3. **Problems with compliance.** Only 50% of persons who begin an exercise program adhere to it for more than 6 months.

a. Physicians may need to help **tailor exercise programs for individual patients** to participate in activity that is sustained in the long-term.

b. As for healthy persons, **precautions** must be taken to **prevent injury**. The current guidelines may be **slightly modified for elderly exercisers** to emphasize a longer warm-up period to enable musculoskeletal and cardiorespiratory readiness for exercise and an adequate cool-down period to help dissipate heat.

VI. NOVEL RISK FACTORS. Screening studies have shown that HTN, hyperlipidemia, tobacco use, family history, and diabetes are predictive of less than half of all future cardiovascular events. Among patients with premature atherosclerosis, the predictive value of these traditional cardiovascular risk factors is limited. Many patients with few traditional risk factors experience life-threatening acute coronary syndromes without prior symptoms of disease. Several potential risk factors have been identified that may enhance risk for CAD. These are levels of C-reactive protein (CRP), lipoprotein(a) or Lp(a), homocysteine, fibrinogen, and myeloperoxidase (MPO), as well as genetic mutations and single-nucleotide polymorphisms (SNPs) in a number of candidate genes.

A. **CRP** is a marker of systemic inflammation. As the role of **inflammation** in the initiation and progression of atherosclerosis becomes better understood, CRP is gaining prominence as an important player in the assessment of cardiovascular risk.

1. **Pathophysiology**

a. CRP has been shown to be an independent risk factor for the development of cardiovascular events in both apparently healthy individuals and in patients with established coronary heart disease. The exact role that CRP plays in this association has not yet been well characterized. Initially, it was believed that CRP provided an indirect measurement of the inflammatory milieu in at-risk individuals. Emerging evidence, however, indicates that CRP itself may have a direct causal influence on the development of atherosclerosis. CRP binds to oxidized LDL, promoting the uptake of LDL by macrophage scavenger cells in the arterial wall and possibly enhancing the atherosclerotic process.

b. The degree of associated risk throughout various levels of CRP, often measured as high-sensitivity C-reactive protein (hsCRP), has been evaluated in several studies.

(1) Men in the Physicians' Health Study with the highest quartile CRP had **three times the risk of MI** and **twice the risk of ischemic stroke** compared with men in the lowest quartile.

(2) In women, the difference is even more pronounced. The relative risk of cardiovascular events in the highest quartile of CRP compared with the lowest quartile of CRP in women is **4.4**.

(3) An increased risk of sudden cardiac death has also been seen in patients with elevated CRP levels.

2. **Clinical use**

a. Standard CRP assays are not sufficiently sensitive to discriminate within the narrow range of CRP values associated with an increase in cardiovascular events. The development of hsCRP assays, however, has made this possible.

AHA/Centers for Disease Control and Prevention (CDC) guidelines have established cut-points of risk for hsCRP: a level of < 1 mg/L is considered low, 1.0 to 3.0 mg/L is average, and > 3.0 mg/L is high and is associated with increased cardiovascular risk. Higher levels (> 10 mg/L) suggest an alternative cause for inflammation, such as infection or underlying rheumatologic illness.

b. When deciding on whether to initiate statin therapy for the primary prevention of coronary events, hsCRP measurement may prove helpful in patients with a moderate level of cardiovascular risk (calculated 10-year major cardiac event risk of 10% to 20%). If found to have an elevated hsCRP level, these patients may benefit from a more intensified therapy, including dietary modifications and, perhaps, statin therapy. In the Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS), lovastatin reduced the incidence of cardiovascular events in patients with low lipid levels if CRP levels were elevated. No improvement was seen in the cohort of patients with low lipid levels and normal CRP values. The Justification for the Use of Statins in Primary Prevention: An Intervention Trial Evaluating Rosuvastatin trial (JUPITER) study targeted individuals with elevated hsCRP levels without hyperlipidemia and showed that statin therapy substantially lowered cardiovascular events in this population.

c. The AHA/CDC panel recommends against widespread screening of the general population. In secondary prevention, hsCRP assessment can be performed, but proven intensified therapy (including statins) should not be withheld based on the level of hsCRP attained. Serial hsCRP measurements should not be used to monitor the effects of lipid treatment.

3. Risk reduction and therapy. Weight loss with caloric-restriction diets has been shown to decrease plasma CRP levels. Additional data indicate that women who exercise regularly have lower CRP levels compared with sedentary women. In primary prevention trials, pravastatin has been shown to reduce CRP levels by about 17%, in a manner independent of LDL lowering. Evidence suggests that simvastatin lowers CRP within the first 2 weeks of therapy, before any LDL-lowering effect is seen. What is not known, however, is whether reducing CRP by any such means confers an independent benefit in regard to lowering cardiovascular morbidity and mortality.

B. Lipoprotein (a) or Lp(a) is identical to LDL, except for the addition of apolipoprotein A (apoA), a highly glycosylated protein. Although it is a lipoprotein, Lp(a) is often considered a **marker of thrombosis**.

1. Pathophysiology

a. There is a striking amino acid sequence homology between apoA and plasminogen, suggesting that Lp(a) may play an important role in the connection between atherosclerosis and thrombosis. **Lp(a) may be atherogenic**; it accumulates in atherosclerotic lesions, binds to apoB-containing lipoproteins and proteoglycans, and can be taken up by foam cell precursors. It may also promote thrombosis when it binds to fibrin and blocks the fibrinolytic action of plasmin.

b. Lp(a) may be more predictive of CAD among younger men, women, and persons with hyperlipidemia.

c. Studies have had mixed results

(1) Cross-sectional and retrospective case–control studies have usually supported the role of Lp(a) in CAD. Lp(a) is a marker among patients at particular risk for poor outcomes, in terms of severity and progression of cardiovascular disease.

(2) Several prospective studies have correlated baseline Lp(a) levels with vascular disease in general.

(3) Other prospective studies have found little or no association between Lp(a) and CAD risk.

d. Few studies have been conducted on the role of Lp(a) in **women**. Cardiovascular risk tends to increase with an Lp(a) value > 30 mg/dL.

2. **Therapy.** Niacin is the only agent currently available that reduces Lp(a). However, due to the multiplicity of lipid effects exerted by niacin therapy, it is unknown if reduction in Lp(a) levels is beneficial. In addition, the atherogenicity of Lp(a) may be modified through **substantial reductions in LDL-C levels**.

C. Homocysteine is a product of folate metabolism. It is derived from the sulfur-containing amino acid methionine and is metabolized through pathways associated with folic acid, vitamin B_6, and vitamin B_{12} as cofactors.

1. **Etiology and pathophysiology**
   - **a.** Elevated plasma homocysteine levels (> 15 μ/L) confer an **independent risk for vascular disease**, according to the cross-sectional and prospective case–control studies. The risk was first identified because of increased thromboembolic events, including MI and stroke, in patients with **homocystinuria**, a rare inherited deficiency of cystathionine β-synthase characterized by very high serum homocysteine levels (> 100 μmol/L).
   - **b.** Elevated homocysteine levels are found among > 20% of patients with atherosclerotic disease, including PVD. In PVD, there may be direct endothelial toxicity, smooth muscle cell proliferation, enhanced LDL oxidation, abnormalities in platelet function, or increased thrombotic risk because of abnormal clotting factors (e.g., factor V and factor VII) or altered secretion of von Willebrand's factor.
   - **c.** The **relative risk of stroke and MI is approximately 2 for homocysteine levels > 15 μmol/L** compared with those < 10 μmol/L. The relative risk of PVD is much greater than 3. Risk enhancement is continuous over the spectrum of homocysteine values.
   - **d.** A meta-analysis of case–control observational studies is less compelling. This study examined patients with a genetic polymorphism of an enzyme involved in folate metabolism; this alteration resulted in elevated homocysteine levels. Individuals with this mutation had only a 16% higher risk of developing CHD compared with normal controls.
   - **e.** **Secondary causes** of increased homocysteine levels include age, male sex, menopause, renal function, and some medications (e.g., niacin, oral contraceptives with estrogen, phenytoin, methotrexate, and theophylline). Thyroid function is also relevant.
   - **f.** The mechanism by which homocysteine appears to promote vascular disease is **unclear**. Elevated homocysteine levels seem to play a role in the production of arterial lesions, but deficiencies of other factors, such as vitamin B_{12} and folic acid, may also be involved, especially in the elderly.
   - **g.** **Possible mechanisms** of increased risk are that hyperhomocysteinemia may impair release of nitric oxide from endothelial cells, stimulate proliferation of atherogenic smooth muscle cells, and contribute to thrombogenesis through activation of protein C.
     - **(1)** Deficiencies in the cofactors lead to elevated serum concentrations of homocysteine, although profound deficiencies are rare among persons with high homocysteine CAD.
     - **(2)** Rare defects in the genes for 5,10-methylene tetrahydrofolate reductase, cystathionine β-synthase (0.5% prevalence), methylene tetrahydrofolate homocysteine methyltransferase (rare), and methionine synthases (rare) can lead to increases in homocysteine.
2. **Laboratory examination.** For patients with abnormal homocysteine values, further evaluation includes thyroid-stimulating hormone, vitamin B_{12}, vitamin B_6, folate, and creatinine.
3. **Trials of homocysteine lowering.** The results of three such large, prospective, randomized trials have been reported in recent years. In the Vitamin Intervention for Stroke Prevention (VISP) trial, patients with a history of stroke were treated with two different doses of folic acid, vitamin B_6, and vitamin B_{12}.

Although a dose-dependent reduction in homocysteine levels was observed, no difference in vascular events was observed between the two groups. The Norwegian Vitamin Trial (NORVIT) randomized patients with history of MI to four different treatment groups: folic acid, vitamin B_6, and vitamin B_{12}; folic acid and vitamin B_{12}; vitamin B_6 alone; or placebo. After a mean 40 months of therapy, homocysteine levels were decreased by 27% in the group treated with folic acid and vitamin B_{12}. However, these subjects had no difference in the development of the primary end point (recurrent MI, stroke, or sudden death from CAD) compared with the placebo group. In the group treated with all three supplements, there was not only a marginally significant trend toward fewer strokes but also a near-significant trend toward more MIs. Finally, the Heart Outcomes Prevention Evaluation 2 (HOPE-2) trial was a mixed primary and secondary prevention trial, treating vascular disease or diabetic patients with either a combination of folic acid, vitamin B_6, and vitamin B_{12} or placebo. Despite a significant decrease in homocysteine levels with active treatment, there was no significant difference in the primary outcome (MI, stroke, or death from cardiovascular causes) when compared with placebo treatment. There was a marginally significant decrease in stroke with vitamin administration. It is unknown whether the negative results of these studies result from incorrectness of the homocysteine atherosclerotic hypothesis or from pathologic effects of vitamin therapy offsetting possible benefit of homocysteine reduction. Regardless, given the lack of benefit (and in some cases, suggestion of harm) provided by folic acid with or without B vitamins, such therapy cannot be recommended for the prevention of cardiovascular disease.

D. Fibrinogen, a large hepatically synthesized glycoprotein, is a clotting factor that activates thrombin, induces platelet aggregation through the glycoprotein IIb/IIIa receptor, and stimulates smooth muscle proliferation.

1. **Etiology and pathophysiology.** There is increasing evidence that **fibrinogen is important in the development of premature atherosclerosis**. The link is likely and plausible.
   a. Several prospective studies, including the Framingham Heart Study, have shown an **impressive relationship between the plasma fibrinogen level and the occurrence of CAD and stroke**. Plasma fibrinogen levels > 350 mg/ dL are powerful independent risk factors for stroke and MI. A high fibrinogen level is an independent risk factor for CAD with a twofold to threefold increase in risk and markedly enhances risk for hypercholesterolemia.
   b. Clinical findings suggest that a **high fibrinogen level may also be a risk factor for the sequelae of CAD**. In the Northwick Park Heart Study, a fibrinogen level in the upper third was associated with a three times higher risk for cardiovascular disease than a plasma level in the lower third. In the Göteburg study, baseline fibrinogen level was significantly related to the incidence of MI and ischemic stroke.
2. **Cofactors.** Determinants of high fibrinogen levels include age, female sex, menopause, African American race, smoking, obesity, stress, use of oral contraceptives, pregnancy, and a consumption of large amounts of dietary fat.
3. **Risk reduction and therapy**
   a. Factors associated with a decrease in fibrinogen level include smoking cessation, physical activity, moderate alcohol intake, normalization of body weight, and postmenopausal hormone replacement.
   b. Although no clinical trial has identified a drug that reduces fibrinogen level safely and selectively, the following medications have been shown to decrease fibrinogen level in various clinical settings: fibrates, pentoxifylline, ticlopidine, *n*-3 polyunsaturated fatty acids, and anabolic steroids.

E. Myeloperoxidase. As discussed previously, inflammation plays a major role in the pathogenesis of CAD and the development of MI. MPO is a protein with enzymatic activity that is released during activation and degranulation of neutrophils and monocytes. For patients in the emergency department with chest pain, serum levels of MPO have been shown to predict risk for MI at 30 days and 6 months, even in the absence of myocardial necrosis. In patients with non–ST-elevation MI, MPO levels have recently been shown to predict 30-day risk of recurrent nonfatal MI or hospitalization for acute coronary syndrome.

F. Nonlipid genetic factors. Although a familial predisposition for CAD has been well documented, little is known about the causative factors leading to premature events in such kindreds. In one family, a seven–amino acid deletion in the gene encoding the MEF2A transcription factor was found to confer autosomal dominant susceptibility to CAD and MI. The thrombospondins are a family of glycoproteins that play a pivotal role in cell adhesion, vascular integrity, and thrombosis. SNPs in thrombospondin genes have been linked to premature atherosclerosis and MI, providing another example of how genetic variations may contribute to the development of coronary disease. Recently, the general excitement regarding genetics of CAD has been somewhat tempered by publications of negative findings. Nevertheless, the identification of genetic risk factors for cardiovascular disease and the elucidation of their mechanism of risk elevation are still among the newest and most promising areas of translational cardiology research.

Diabetes and the Heart

I. INTRODUCTION. The presence of type 1 diabetes mellitus (T1DM) or type 2 diabetes mellitus (T2DM) confers a marked increase of risk of coronary artery disease (CAD) development. **CAD accounts for as many as 80% of deaths among individuals with diabetes, compared with 30% in those without diabetes**. The prevalence of T2DM, which correlates closely with overweight and obesity, has shown a sharp rise over recent decades. Consequently, the management of diabetes, in parallel with the management of nonglycemic CAD risk factors including hypertension, dyslipidemia, and obesity, has become a prime focus in both the primary and secondary prevention of cardiovascular events. Significant uncertainty remains regarding the impact of tight glucose control on future cardiovascular events and the optimal glucose-lowering drug regimen. The revascularization strategies best suited to individuals with diabetes are also an area of ongoing research.

II. EPIDEMIOLOGY

A. Epidemiology of diabetes

1. Diabetes has been described as a worldwide epidemic and is now one of the most common chronic diseases in both developed and developing nations. This rise in prevalence is driven partly by rising levels of obesity, physical inactivity, and

TABLE 45.1 List of Countries with the Highest Numbers of Estimated Cases of Diabetes for 2000 and 2030

	2000		2030	
	Country	People with diabetes (millions)	Country	People with diabetes (millions)
1	India	31.7	India	79.4
2	China	20.8	China	42.3
3	United States	17.7	Unites States	30.3
4	Indonesia	8.4	Indonesia	21.3
5	Japan	6.8	Pakistan	13.9

From Wild S, Roglic G, Green A, et al. Global prevalence of diabetes. *Diabetes Care.* 2004;27(5):1047–1053.

urbanization, coupled with the aging population and greater longevity for patients with diabetes due to advances in diabetes management. The International Diabetes Federation reported that there were 30 million individuals with diabetes worldwide in 1985. The most recent analysis of data suggests this had grown to 171 million adults over 20 years in 2000 (1). If the age-specific prevalence remains constant, there will be a projected doubling in global diabetes cases between 2000 and 2030, bringing the expected total to a staggering 366 million.

2. The greatest burden of diabetes lies in developing countries, as illustrated in Table 45.1. India and China are notable for the exceptionally high prevalence in 2000 (31.7 and 20.8 million, respectively, compared with 17.7 million in the United States). The projected 2030 figures for individuals with diabetes are 79.4 million in India, 42.3 million in China, and 30.3 million in the United States (1). In developing countries, the majority of people with diabetes are in the 45- to 64-year age range. In contrast, the majority in developed countries are over 64 years of age.
3. **T2DM was once considered to be a disease of adulthood, but it has recently been recognized with increased frequency in children and adolescents**, particularly within some ethnic groups such as Native Americans (2). Ten years ago, 3% of new-onset diabetes in adolescents was type 2; currently, 45% of cases are designated T2DM (3). The onset of diabetes in the second decade of life coincides with the physiological occurrence of pubertal insulin resistance. Up to 75% of young people diagnosed with T2DM have a first- or second-degree relative with the condition.
4. **Diabetes prevalence is higher in men than in women, but there are more women in total with diabetes.** T2DM, in contrast to T1DM, is notable for its close association with conditions such as hypertension, dyslipidemia, and obesity, which further raises the impact of T2DM on the health outcomes of affected individuals.
5. In the United States, 95% of diabetes cases are T2DM, but T1DM has also shown increased incidence over recent years. The increase occurs largely in the youngest individuals (< 5 years) and those with moderate genetic susceptibility (4). A variety of environmental factors and the increasing incidence of childhood obesity are currently being studied as potential causes.

B. Spectrum of insulin resistance to T2DM

1. There is a continuum between the early pathological features of disordered glucose metabolism and T2DM.

TABLE 45.2 Criteria for the Diagnosis of Diabetes and Prediabetes

Diabetes:

- **HbA1c** ≥ 6.5%

or

- **Fasting plasma glucose** ≥ 126 mg/dL (7.0 mmol/L)

or

- **2-H plasma glucose** ≥ 200 mg/dL (11.1 mmol/L) in 75-g oral glucose tolerance test

or

- **Random plasma glucose** ≥ 200 mg/dL (11.1 mmol/L) with classic hyperglycemia signs/symptoms

In the absence of unequivocal hyperglycemia, results should be confirmed by a repeat test.

Prediabetes:

- **HbA1c** 5.7–6.4%

or

- **Fasting plasma glucose** 100–125 mg/dL (5.6–6.9 mmol/L) = impaired fasting glucose

or

- **2-H plasma glucose** 140–199 mg/dL (7.8–11.0 mmol/L) in 75-g oral glucose tolerance test = impaired glucose tolerance

From American Diabetes Association. Standards of Medical Care in Diabetes 2011. *Diabetes Care.* 2011;34(suppl 1):S11–S61.

a. A diagnosis of diabetes can be made on the basis of a fasting blood glucose ≥ 126 mg/dL (7.0 mmol/L) or a 2-hour plasma glucose of ≥ 200 mg/dL (11.1 mmol/L) during a 75-g oral glucose tolerance test. A HbA1c ≥ 6.5% has now been added to the ADA criteria for the diagnosis of diabetes. In the absence of unequivocal hyperglycemia, a positive result for any of these criteria should be confirmed on repeat testing. In the setting of classic hyperglycemic symptoms, a single random glucose ≥ 200 mg/dL is considered diagnostic (5). These diagnostic criteria are summarized in Table 45.2.

b. It is now recognized that the microvascular and macrovascular complications of diabetes are not limited only to individuals meeting the diagnostic criteria for established diabetes. The progression from normal glucose tolerance to T2DM involves intermediate stages of impaired fasting glucose (IFG) and impaired glucose tolerance (IGT), also collectively termed "prediabetes." This pathological continuum arises from dysregulation of the balance between insulin sensitivity and insulin secretion.

c. There is usually a long phase of asymptomatic pathology prior to the development of overt T2DM. Longitudinal studies suggest that insulin resistance onset occurs 10 to 20 years prior to the diagnosis of diabetes and is the best predictor of whether an individual will develop T2DM later. Insulin resistance places pressure on the pancreatic β-cells to augment secretion of insulin and, therefore, promotes β-cell dysfunction. Once the β-cell is unable to compensate sufficiently for the peripheral insulin resistance state, progression to T2DM will ensue. The underlying etiology of T2DM is complex, with both environmental and genetic predisposing factors promoting insulin resistance and β-cell dysfunction.

d. The most notable epidemiological evidence regarding the impact of prediabetes states comes from the DECODE group. They have demonstrated that subjects without a diagnosis of diabetes have no threshold level of fasting or 2-hour postload glucose concentration above which the risk of all-cause or cardiovascular mortality death increased sharply. The relationship between 2-hour postload glucose and cardiovascular mortality was linear, with a continuum of risk extending into and below the prediabetes glucose range (6).

e. Current interpretations of data sets suggest that the cardiovascular effects of postprandial or postglucose challenge hyperglycemia are greater than those of IFG (7). During the prediabetes phase, the cardiovascular event rate is modestly increased. There is evidence for a higher mortality in individuals with IGT compared with those with IFG, which is independent of HbA1c or fasting blood glucose (8). The Emerging Risk Factors Collaboration found that individuals without a diagnosis of diabetes showed only a modest nonlinear correlation between fasting blood glucose and cardiovascular end points; postprandial glucose was not investigated.

f. There is evidence that the pathogenic effect of hyperglycemia on the endothelial cells already exists in the prediabetes stage.

2. The full transition from the early metabolic abnormalities of prediabetes to established diabetes probably occurs in about two-thirds of individuals.

a. There is interest in determining **interventions that may decrease the likelihood of progression to diabetes** or reduce the future cardiovascular event rate once diabetes occurs. The Diabetes Prevention Program Research Group randomly assigned 3,234 participants without diabetes, but with elevated fasting and postload glucose concentrations, to placebo versus metformin (850 mg twice daily) versus a lifestyle modification program promoting exercise and weight loss (9). The incidence of diabetes over an average follow-up of 2.8 years was 11.0, 7.8, and 4.8 cases per 100 person-years in the placebo, metformin, and lifestyle groups, respectively. **The lifestyle intervention was significantly more successful in preventing diabetes than the metformin strategy**. Also of note is the STOP-NIDDM trial, which randomized individuals with IGT to acarbose (which primarily affects postprandial glycemia) or placebo (10). Patients in the acarbose group were observed to have a lower rate of diabetes diagnosis than those receiving placebo. Furthermore, a lower rate of cardiovascular disease and hypertension over a 3.3-year mean follow-up period was reported in the acarbose group (11).

C. Impact of diabetes on heart disease

1. Both T1DM and T2DM confer significantly elevated risks of CAD, acute coronary syndromes, post–myocardial infarction (MI) complications, heart failure, and probably also sudden cardiac death. In addition, the incidences of peripheral arterial disease, stroke, and end-stage renal failure are elevated in individuals with diabetes. The cardiovascular complications of T2DM account for the majority of the socioeconomic burden of this chronic disease on both individuals and society.

a. **As many as 80% of individuals with diabetes will die from cardiovascular causes**. Per the Framingham Heart Study, the risk of CAD is doubled in men and tripled in women with diabetes, compared with age-matched subjects without diabetes.

b. In the modern era of drug-eluting stents and dual antiplatelet therapy, the mortality associated with CAD is falling overall. However, women with diabetes were observed to have a rise in CAD mortality in the period 1995 to 2003 (12).

c. More recently, the Emerging Risk Factors Collaboration undertook a large meta-analysis that demonstrated a twofold excess risk of outcomes such as coronary heart disease, coronary death, and nonfatal MI among individuals with established diabetes (13). They also found diabetes to be a third more strongly related to fatal than to nonfatal MI, possibly suggesting more severe manifestations of

coronary disease in those with diabetes. Hazard ratios (HRs) were particularly elevated for cardiovascular disease among individuals with diabetes who were female, younger, and non-smokers or had lower-than-average blood pressure.

d. Patients with diabetes present differently from those without diabetes and are much more likely to experience an acute coronary syndrome without chest pain, known as "silent ischemia."

e. Various angiographic trials have demonstrated that patients with **diabetes undergoing percutaneous coronary intervention (PCI) or coronary artery bypass surgery (CABG) tend to have significantly more severe CAD**, with a preponderance of multivessel disease and greater severity of lesions than those without diabetes. Despite the more severe plaque burden, diabetes correlates with lesser collateral vessel formation.

f. A particularly high risk is observed among individuals with T2DM following their first cardiovascular event. Indeed, there are multiple studies suggesting poorer outcomes following cardiovascular events, even with revascularization, for individuals with diabetes compared with those without. Cubbon et al. (14) reported that diabetes conferred a higher 30-day mortality after urgent PCI (9.4% patients with diabetes vs. 5.9% without diabetes, $p < 0.001$).

g. Post-MI complications and mortality in patients with diabetes correlate with post-MI ejection fraction and the presence of multivessel coronary disease. **Cardiogenic shock is more common and more severe in post-MI patients with diabetes**. The higher in-hospital mortality among the post–acute coronary syndrome (ACS) population with diabetes is largely related to the greater incidence of acute decompensated heart failure and to a lesser extent the increased risk of reinfarction and infarct extension.

h. The CAD mortality arising from T1DM has also been studied. Laing et al. reported a prospective study of 23,751 individuals with T1DM where subjects were followed for up to 29 years (15). As is typical of a T1DM cohort, the relatively young age correlated with a low event rate. However, their CAD risk was several times higher than that of a matched population without diabetes.

i. There is now sufficient literature to conclude that **chronic hyperglycemia per se, rather than the associated cardiovascular risk factors, has a pathogenic role in the development of vascular disease in diabetes**.

D. Risk factors for CAD in patients with diabetes

1. The risk factors that predispose individuals with diabetes to develop cardiovascular disease are the same as those that raise cardiovascular risks in those without diabetes. However, the prevalence of known major risk factors for CAD is generally amplified among persons with diabetes. Given the overall higher cardiovascular risk conferred, the benefits of tighter risk factor control may be greater in those with diabetes than those without. The potential gains of aspirin, attaining a normal body weight and nonsmoking status, tight blood pressure control, and aggressive lipid management in diabetes have been the subject of several recent trials.

2. a. Dyslipidemia

(1) This is one of the most profound risk factors among individuals with diabetes. Diabetes is associated with small, dense low-density lipoprotein (LDL) particle composition, increased levels of apolipoprotein B and E, low levels of high-density lipoprotein (HDL) cholesterol, and high triglyceride (TG) levels. These lipid composition abnormalities cluster with insulin resistance and abdominal adiposity and appear to induce endothelial dysfunction and an increased susceptibility to thrombosis.

(2) Lipid-lowering therapy is now a cornerstone of T2DM management. In the Scandinavian Simvastatin Survival Study (4S), there was a 55% reduction in cardiovascular events among subjects with diabetes and a 25% reduction in the CARE trial. The National Cholesterol Education Program

(NCEP) considers diabetes a CAD equivalent in its Adult Treatment Panel III guidelines. Hence, a target of < 100 mg/dL—with an optional goal of < 70 mg/dL—is recommended (16). Statins are considered first-line agents to achieve these targets. Niacin may be of use in elevating HDL levels. Bile acid binding resins (along with thiazides, estrogens, and glucocorticoids) may increase TG levels and therefore should be avoided where possible.

b. Hypertriglyceridemia

(1) Elevated fasting TG levels are characteristic of the lipid panel in diabetes and **constitute an independent cardiovascular risk factor**. Hypertriglyceridemia correlates with abdominal adiposity.

(2) Fibrates have traditionally been considered an appropriate therapy to target hypertriglyceridemia and have often been added to statin therapy for this indication. The Helsinki Heart Study demonstrated the benefit of fibrates in a primary prevention trial to reduce cardiovascular end points (but not mortality), and the **VA HDL Intervention Trial (VA-HIT)** showed outcomes benefit in a secondary prevention setting. However, the lipid arm of the **ACCORD (Action to Control Cardiovascular Risk in Diabetes) trial** did not demonstrate any benefit for subjects with T2DM in the addition of fenofibrate to simvastatin. The significant rhabdomyolysis risk with a fibrate and statin combination should also be considered.

c. Hypertension

(1) The prevalence of hypertension is increased in individuals with diabetes compared with those without. The presence of an elevated blood pressure serves as at least as strong a risk factor for CAD as it does for individuals without diabetes.

(2) There are multiple large trials supporting the benefit of blood pressure lowering in subjects with diabetes. In the UKPDS, lowering the blood pressure to a mean of 144/82 mm Hg (compared with 154/87 mm Hg) significantly reduced strokes, diabetes-related deaths, and heart failure, as well as microvascular complications. In that trial, there did not appear to be an outcome benefit between captopril and atenolol (17). However, several trials since have demonstrated the renal protective effects of angiotensin-converting enzyme (ACE) inhibitors (or angiotensin receptor antagonists) over alternate agents, which has firmly established them as the first-line antihypertensives in diabetes.

The **Hypertension Optimal Treatment (HOT) trial** demonstrated the benefit of a lower diastolic target. Among the 3,000 subjects with diabetes, but not in those without diabetes, the relative cardiovascular risk was significantly reduced in the ≤ 80 mm Hg group, compared with the ≤ 90 mm Hg group (18). Major guidelines suggest a target blood pressure in patients with diabetes of < 130/80 mm Hg. The ACCORD trial randomized subjects with diabetes to a target systolic blood pressure of < 120 mm Hg or < 140 mm Hg. The lower target group showed no difference in the primary cardiovascular outcomes end point but did have a significantly lower stroke rate; however, this was at the expense of significantly more adverse drug events and an increased risk of a creatinine rise of > 1.5 mg/dL (19). There is currently insufficient evidence to recommend ACE inhibitors in normotensive patients with diabetes without microalbuminuria.

d. Tobacco. There is evidence that smokers with diabetes have a markedly increased risk of MI and peripheral arterial disease. Lipid abnormalities and the development of atherosclerotic plaques appear to be promoted by smoking in the setting of diabetes.

e. Obesity

(1) The prevalence of obesity has more than doubled in the United States since 1980. Obesity and overweight are typically defined in terms of

body mass index (BMI), with overweight being 25 to 30 kg/m^2, class I obesity 30 to 35 kg/m^2, class II obesity 35 to 40 kg/m^2, and class III obesity > 40 kg/m^2. Waist circumference and waist-to-hip ratio better reflect abdominal adiposity and are more reliable predictors of CAD outcomes than BMI (20). Obesity is an important determinant of cardiovascular health and is associated with widespread alterations in cardiac and vascular structure and function. It has been shown to be an independent risk factor for the development of cardiovascular disease. **T2DM correlates closely with obesity, especially central obesity**.

(2) Caloric restriction, behavior modification, and increased physical activity form the basis of weight management programs. Unfortunately, sustained weight loss is difficult to achieve with these conservative measures. Several medications have been marketed for temporary assistance with weight loss.

(a) Sibutramine is a combined inhibitor of neuronal norepinephrine, serotonin, and, to a lesser degree, dopamine reuptake. It is a sympathomimetic and therefore increases heart rate and blood pressure, leading to concerns reading its cardiovascular safety profile. It has recently been withdrawn from the market in multiple countries including the United States.

(b) Ephedrine and ephedra alkaloids ("ma huang") are sympathomimetic amines with a prolonged duration of action and increased peripheral effects. Due to safety concerns, ephedrine with or without caffeine and the ephedra alkaloids are not approved for treatment of obesity.

(c) Phentermine and diethylpropion are the only sympathomimetic drugs currently approved for the short-term treatment of obesity. Their use is not widespread.

(d) Orlistat is currently the only drug that is available for modulation of fat digestion. It inhibits pancreatic lipases, thus increasing the proportion of fat that is not completely hydrolyzed and is fecally excreted. The recommended prescription dose is 120 mg three times daily. A 60 mg over-the-counter version is available in some countries, including the United States. Major side effects include abdominal cramps, flatus, fecal incontinence, diarrhea, and oily stools; there is a rare association with severe liver injury.

Multiple trials have demonstrated a greater initial weight loss with orlistat, compared with placebo, and also slower weight regain in the longer term. In obese individuals with diabetes, orlistat not only promotes weight loss but also decreases A1c at 1 year in comparison with placebo (21).

(e) Other drugs that may have effects in supporting weight loss include antidepressants such as fluoxetine, sertraline, bupropion; anti-epileptics such as topiramate and zonisamide; and diabetes medications including metformin and the glucagonlike peptide (GLP) analogs.

(3) There is growing evidence regarding the beneficial effects of significant weight loss achieved by bariatric surgery on glucose metabolism. Bariatric surgery is generally restricted to individuals with BMI > 40 kg/m^2 or BMI 35 to 40 kg/m^2 with co-existing medical conditions such as diabetes, although the 2005 revision of the NIH consensus statement by the American Society for Bariatric Surgery expanded the indications to BMI 30 to 35 kg/m^2 with comorbidities.

(a) Bariatric surgery options include malabsorptive procedures such as the Roux-en-Y gastric bypass (currently accounting for the majority of bariatric operations in the United States) and restrictive procedures such as laparoscopic adjustable gastric bands and sleeve gastrectomy. The most recent data from the Longitudinal Assessment of Bariatric Surgery Consortium show a 30-day mortality rate of < 1% (22).

(b) Weight loss post bariatric surgery is typically expressed in terms of "excess weight," which refers to the difference between the actual and the ideal weights for an individual. Weight loss after malabsorptive bariatric surgery tends to reach a nadir at 12 to 18 months with an average of 70% excess body weight loss and a 35% decrease in BMI, with an approximate 10% weight regain in the following 10 years (23).

(c) A meta-analysis of 22,000 patients demonstrated that an average excess body weight loss of 61% was accompanied by significant improvements in T2DM, hypertension, dyslipidemia, and obstructive sleep apnea. Indeed, bariatric surgery has demonstrated an ability to completely reverse established diabetes in a large number of subjects. In the Swedish Obese Subjects Study (23), a prospective, nonrandomized, intervention trial of 4,047 obese subjects, 72% of individuals with diabetes who chose the bariatric surgery option showed reversal of their diabetes at 2 years, compared with 21% of those who followed a conservative weight loss regimen of diet and exercise. At 10 years follow-up, diabetes was reversed in 36% of the bariatric surgery group and 13% of the control group. In a smaller study of 165 obese patients with diabetes by Pories, 83% showed diabetes remission at a mean of 9.4 years (24). In the recent STAMPEDE trial, 150 patients with uncontrolled T2DM and a BMI between 27 and 43 kg/m^2 were randomized to intensive medical therapy alone, versus medical therapy plus Roux-en-Y gastric bypass or sleeve gastrectomy. The proportion of patients with HbA1c ≤ 6.0% at 12 months was 12% in the medical therapy group, versus 42% in the gastric-bypass group ($p = 0.002$) and 37% in the sleeve-gastrectomy group ($p = 0.008$).

(d) There is growing evidence that there are both substantial modifications in the traditional CAD risk factors post bariatric surgery and that these risk modifications translate to a cardiovascular outcome benefit. The largest study of Framingham risk scores and actual cardiovascular events after gastric bypass involved 500 patients (without a control group) (25). At 1 year, the mean excess body weight loss was 68.7% ± 22%. The diabetes prevalence fell from 28% to 6% ($p = 0.001$). The average 10-year absolute cardiovascular event risk, as estimated from the Framingham data, was 5.4% at baseline. This reduced to 2.7% at 1 year postsurgery ($p = 0.001$). The actual rate of cardiovascular events observed in this cohort postoperatively was only 1%.

3. Multifactorial risk factor interventions should be targeted in all patients with diabetes, regardless of whether this is a primary or a secondary prevention strategy.

a. The Steno-2 trial randomized 160 patients with T2DM and microalbuminuria to intensive versus conventional therapy for a mean period of 7.8 years (26). The trial was designed to evaluate the effect on cardiovascular events of an intensified, targeted, multifactorial intervention comprising behavior modification and polypharmacologic therapy aimed at several modifiable risk factors in patients with T2DM.

b. The intensive management regimen included dietary fat restriction, 30 minutes of exercise three to five times per week, smoking cessation, ACE inhibitors or angiotensin receptor blocker administration irrespective of blood pressure, additional agents to target blood pressure < 130/80 mm Hg, 150 mg aspirin, stepwise glycemia management to target A1c < 6.5%, statins for hyperlipidemia, and fibrates for isolated hypertriglyceridemia. The intensive group achieved significantly lower blood pressure, HbA1c, LDL, and TGs. There was an absolute risk reduction of 20% in cardiovascular events.

c. The subjects were then followed up for a further mean of 5.5 years, at which point the primary end point of all-cause mortality was assessed (27).

Significant differences in blood pressure, A1c, LDL, and TGs were absent by this later follow-up point. The primary end point at 13.3 years was time to all-cause death, and an absolute risk reduction of 20% was found. Even beyond the period of tight risk factor control, the Kaplan-Meier curves for the first cardiovascular event continued to diverge. During the mean 13.3-year follow-up period, the mortality rate among the conventional therapy subjects was 50%, a finding that highlights the poor overall outcomes in patients with diabetes who are not intensively managed.

d. This study established that there were long-term benefits to aggressive multifaceted risk factor management, and that tight glycemic control and treatment with aspirin, antihypertensives, and lipid-lowering drugs appeared to be additive. Therefore, current society and national guidelines stress the importance of a broad approach to targeting multiple cardiovascular risk parameters. This body of evidence is much more firmly established than that regarding any benefit from tight glycemic control as a single approach to reducing cardiovascular risk.

E. Metabolic syndrome

The term "metabolic syndrome" describes the clustering of several of these cardiovascular risk factors in association with impaired glucose metabolism. There are slightly differing diagnostic criteria established by the WHO (28), the AHA and IDF (29), and the NCEP (30). The 2009 joint AHA/IDF criteria are summarized in Table 45.3. The value of the concept of the metabolic syndrome may lie in the emphasis it has placed on considering the patient as a whole and also the concept of abdominal adiposity being the more relevant predictor of CAD than BMI. However, several commentators have recently challenged the relevance of the metabolic syndrome, as it appears that accounting for the presence of the metabolic syndrome does not serve as a stronger predictor of cardiovascular risk than the individual component parameters (31).

F. Role in pathology of atherosclerosis

1. Diabetes accelerates the atherosclerosis process. Autopsy series have revealed more diffuse coronary involvement, greater severity of vessel stenosis, and more severe left main disease in persons with diabetes, compared with those without. Similarly, adverse coronary anatomy findings have been observed in autopsy studies of patients with a history of childhood onset of T1DM who died before the age of 40 years. The pathophysiology of atherosclerosis in diabetes remains incompletely understood but is thought to involve the hyperglycemia, lipid abnormalities, and

TABLE 45.3 Joint AHA and IDF Criteria for the Diagnosis of the Metabolic Syndrome

Metabolic syndrome

- **Waist circumference** in excess of population- and country-specific dimensions
- **Elevated triglycerides** ≥ 150 mg/dL (1.7 mmol/L), *or drug treatment for hypertriglyceridemia*
- **Low HDL** < 40 mg/dL (1.0 mmol/L) in males or < 50 mg/dL (1.3 mmol/L) in females, *or drug treatment for low HDL*
- **Elevated blood pressure** systolic ≥ 130 mm Hg and/or diastolic ≥ 85 mm Hg, *or antihypertensive drug treatment in a patient with diagnosis of hypertension*
- **Elevated fasting glucose** ≥ 100 mg/dL (5.6 mmol/L), *or drug treatment for hyperglycemia*

dysfunctional endothelial and vascular smooth muscle function, coupled with a propensity for inflammation, thrombosis, and platelet activation.

2. It is recognized that the synthesis of nitric oxide (NO) by the vascular endothelium is reduced in subjects with diabetes. NO is among several key substances that maintain healthy endothelial function, which includes freedom from adhesion molecule activation, leukocyte diapedesis, platelet aggregation, and activation of thrombosis. However, the bioavailability of NO is adversely affected by hyperglycemia, high levels of free fatty acids, and insulin resistance. Current research reveals the impact of excessive oxidative stress (which can be induced by hyperglycemia, fatty acids, or insulin resistance) on NO production and also on the generation of advanced glycation end products, which are suspected to mediate various negative cellular effects in diabetes. Reactive oxygen species also activate protein kinase C with wide-ranging effects on cellular metabolism, including activation of the PI3K pathway, which has a role in mediating cell adhesion and migration. The ability of NO to act on vascular smooth muscle and cause vasodilation is reduced; endothelial cell dysfunction in diabetes is coupled with increased production of vasoconstrictors such as prostanoids and endothelin.

   Another key pathogenic feature of atherosclerosis in diabetes is the PI3K- and nuclear factor κB–stimulated alterations in adhesion molecule expression on the endothelial surface. This causes the endothelium to become more adherent to passing cells, and selectins on the surface of leukocytes attach to receptors such as ICAM-1 (intercellular adhesion molecule 1) and VCAM-1 (vascular cell adhesion molecule 1) and migrate into the intima. Here monocytes take on oxidized LDL and become macrophage foam cells, which are instrumental in the development of an atherosclerotic plaque. The tendency toward small, dense LDL particles in diabetes is another factor contributing toward atherosclerosis. Smooth muscle cell proliferation ensues, leading to deposition of collagen and other extracellular matrix proteins into the plaque.

   Platelet function is also abnormal in diabetes, with overexpression of the glycoprotein IIb/IIIa receptor promoting inappropriate platelet adhesion and activation. Upregulation of multiple coagulation factors such as factor VII, thrombin, tissue factor, and plasminogen activator inhibitor-1 increases the tendency toward clotting, therefore contributing to the risk of thrombosis at the site of a plaque rupture or stent placement.

III. MICROVASCULAR TRIALS (as summarized in Table 45.4)

A. The role of tight control of glycemia was firmly established in the 1990s with the publication of **two large trials demonstrating decreases in microvascular complications—primarily nephropathy and retinopathy—with lower glucose goals**.

1. The Diabetes Control and Complications Trial (DCCT) recruited 1,441 patients with T1DM, of whom 726 had no retinopathy at baseline and 715 had mild retinopathy (32). Subjects were randomly assigned to an external insulin pump or three or more daily insulin injections to target a fasting glucose < 6 mmol/L. Conventional therapy had no glucose goals beyond those needed to prevent symptoms and comprised one or two daily injections of insulin. The two treatment groups were followed for a mean of 6.5 years between 1983 and 1993, with the mean HbA1c attained being 7.4% and 9.1%, respectively. In the primary prevention cohort (those without baseline retinopathy), intensive therapy reduced the adjusted mean risk of retinopathy development by 76%. With the two cohorts combined, intensive glucose control reduced the occurrence of microalbuminuria by 39%.
2. The UK Prospective Diabetes Study (UKPDS) recruited 5,102 newly diagnosed T2DM patients from 1977 to 1991 with a median baseline HbA1c of 9.1% (33). The 4,209 patients who could not be controlled on diet alone were managed with differing therapies to determine if there were any specific advantages

TABLE 45.4 Characteristics of the Major Randomized Controlled Trials of Intensive Glucose Control in Type 2 Diabetes

	UKPDS 33	ACCORD	ADVANCE	VADT
Participants (*n*)	3,867	10,251	11,140	1,791
Diabetes duration (y)	0	10	7.9	11.5
Mean age (y)	53	62	66	60
History of CV disease (%)	Not reported	35	32	40
Duration of intervention (y)	10.0	3.5	5.0	5.6
Intensive group treatment	Sulfonylurea or insulin	Any oral drugs, insulin (91% rosiglitazone)	Gliclazide, other drugs including insulin	Glimepiride or metformin, plus rosiglitazone, or insulin
Standard group treatment	Diet	Any oral drugs, insulin (57% rosiglitazone)	Any oral drugs, insulin	Glimepiride or metformin, plus rosiglitazone, or insulin
Intensive group goal	FPG < 6.0 mmol/L	A1c < 6.0%	A1c ≤ 6.5%	1.5% absolute A1c reduction, cf. standard group
Standard group goal	FPG 6.1–15.0 mmol/L	A1c 7.0–7.9%	Local standards	Local standards
Baseline median A1c (%)	7.1	8.1	7.5	9.4
Achieved median A1c (%)	7.0 vs. 7.9	6.4 vs. 7.5	6.5 vs. 7.3 (mean)	6.9 vs. 8.4
Primary CV outcome	MI and sudden cardiac death	Nonfatal MI or stroke, or CV mortality	Nonfatal MI or stroke, or CV mortality	Nonfatal MI or stroke, CV mortality, heart failure, vascular surgery, inoperable CAD, amputation
Hazard ratio for primary outcome	16% risk reduction ($p = 0.052$)	0.90 (95% CI 0.78–1.04)	Macrovascular 0.94 (95% CI 0.84–1.06)	0.88 (95% CI 0.74–1.05)
Hazard ratio for death	0.87 ($p = 0.006$)	1.22 (95% CI 1.01–1.46)	0.93 (95% CI 0.83–1.06)	1.07 (95% CI 0.80–1.42)

or disadvantages between glucose-lowering agents. A total of 342 obese subjects were allocated to the metformin group; of the remaining patients, 30% were randomized to conventional therapy and 70% to insulin or a sulfonylurea. The intensive group aimed for a fasting plasma glucose < 6 mmol/L. The median HbA1c achieved was 7.0% in the tight control group versus 7.9% in the conventional group. There was a significant 25% risk reduction (95% confidence interval [CI] 7% to 40%) in the end point of renal failure or death from renal failure, vitreous hemorrhage, or photocoagulation in the intensive control group.

In summary, the two large trials published in the 1990s, DCCT and UKPDS, showed significant improvements in microvascular outcomes with tighter glycemic control in T1DM or T2DM.

IV. MACROVASCULAR TRIALS

A. Despite the convincing evidence for a reduction in microvascular complications, the relationship between glycemia and cardiovascular events remained unclear, with neither DCCT nor UKPDS showing a definitive advantage in terms of cardiovascular outcomes or mortality.

B. The DCCT did not reveal a significant difference in macrovascular outcomes between the two treatment groups, but this relatively young cohort of T1DM patients would have been expected to have a low event rate. However, intensive glycemic control did reduce hyperlipidemia development.

C. The UKPDS revealed a nonsignificant 16% risk reduction (95% CI 0% to 29%, $p = 0.052$) for fatal or nonfatal MI, or sudden death, with intensive management. In those subjects with > 120% ideal body weight who were allocated to the metformin strategy, there were significant benefits in terms of diabetes-related end points and all-cause mortality and a 39% risk reduction in MI. However, these results should be interpreted with caution due to the small numbers in the metformin subgroup.

D. Two follow-up studies, and three new trials of intensive glucose control, sought to clarify the relationship between glucose control and cardiovascular events. Both the DCCT and the UKPDS cohorts were followed up for more than a decade from recruitment and their macrovascular outcomes assessed.

1. The DCCT follow-up, known as EDIC (Epidemiology of Diabetes Interventions and Complications), monitored 93% of the original cohort until 2005, for a mean of 17 years of follow-up (34). Beyond 1993, DCCT subjects were placed onto whatever diabetes regimen their physician deemed appropriate, and so the distinction between standard and intensive management strategies was lost and the mean HbA1c's were the same. However, there was emergence of a macrovascular risk reduction in the group that had received the period of tight control earlier in the course of their T1DM; a 42% risk reduction for all cardiovascular events (95% CI 9 to 63, $p = 0.02$) was observed in this group.

2. Similarly, the UKPDS subjects were invited for posttrial monitoring, with 3,277 patients attending annual clinics for a further 5 years (35). No attempts were made to maintain their previously assigned therapies, and indeed there was no persisting difference in A1c between groups at 1 year after initial trial conclusion. Data were then analyzed by original trial groupings. The sulfonylurea/insulin group showed a sustained decrease at 10 years for MI (15%, $p = 0.01$) and death from any cause (13%, $p = 0.007$). The metformin group showed a significant risk reduction in MI (33%, $p = 0.005$) and all-cause mortality (27%, $p = 0.002$).

3. The DCCT/EDIC and UKPDS follow-up findings can be interpreted as showing "legacy" effects, whereby tighter management of glycemia early in the disease course confers cardiovascular and survival benefits more than a decade later. However, these potential delayed macrovascular benefits appear to be modest in comparison with long-term aggressive management of blood pressure and LDL.

E. Three further large trials added additional information regarding the potential relationship between glycemic control and cardiovascular outcomes.

1. The Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation (ADVANCE) trial randomized 11,140 patients with T2DM to standard versus intensive glucose control (36). Intensive control was achieved with the use of gliclazide (a sulfonylurea) plus other agents as necessary to achieve a HbA1c ≤ 6.5%. After 5 years' median follow-up, the mean A1c was 7.3% in the standard group and 6.5% in the intensive group. Insulin was prescribed for 40.5% and 24.1% of patients in the intensive group and the standard control group, respectively. There was a decrease in the incidence of microvascular events (primarily macroalbuminuria) but no significant effect of the type of glucose control on major macrovascular events (HR with intensive control 0.94), death from cardiovascular causes (HR 0.88), or death from any cause (HR 0.93). Of relevance, the nonglycemic risk factors were not fully optimized in many participants, with a mean systolic blood pressure of 135.5 ± 17.6 in the intensive glucose group and 137.9 ± 18.4 in the standard group and an LDL mean of around 120 mg/dL ± 20 in both groups.
2. The ACCORD trial also tested the effects of tight glucose control, recruiting a total of 10,251 T2DM patients who were randomized to a target A1c of < 6% versus 7.0% to 7.9% (37). These participants were slightly younger than those studied in ADVANCE; they also tended to be heavier, had a higher median baseline A1c, and were much more likely to be using insulin prior to entry. ACCORD was discontinued at a mean follow-up of 3.5 years due to an increased risk of death in the intensive treatment arm. The primary outcome of nonfatal MI, nonfatal stroke, and cardiovascular mortality occurred in 352 patients in the intensive group versus 371 in the standard group (HR 0.90, 95% CI 0.78 to 1.04, p = 0.16). Hypoglycemia requiring medical attention and weight gain > 10 kg were both more common in the intensive therapy group. The finding of harm with a very aggressive A1c target was surprising and could be related to adverse effects of hypoglycemia, especially in long-standing diabetes—19 of the 41 cardiovascular deaths were attributed to "unexpected or presumed cardiovascular disease," and so could have been hypoglycemia-related. In addition, the average weight gain of 3.5 kg in the intensive control group (presumably drug-mediated) may have impacted on outcomes. It has also been noted that 91.2% of intensive therapy patients were receiving rosiglitazone, which was subsequently associated in other literature with an excess cardiovascular mortality, versus 57.2% of the standard therapy group.
3. The VADT randomly assigned 1,791 predominantly male military veterans who had a suboptimal response to therapy for T2DM to receive either intensive or standard glucose control (38). The mean age was 60 years, 40% had already experienced a cardiovascular event, 52% were receiving insulin, and the mean baseline HbA1c was 9.4%. This high-risk cohort was followed for a mean of 5.6 years, during which time the mean A1c was 6.9% in the intensive group and 8.4% with standard care. However, there was no significant difference observed between the two groups in any component of the primary outcome or in all-cause mortality (HR 1.07, 95% CI 0.81 to 1.42; p = 0.62).

F. The conclusion currently drawn from these studies is that there may be an early window in which tight glycemic control has the potential to achieve cardiovascular outcome benefits more than a decade later. However, ADVANCE, ACCORD, and VADT trials did not demonstrate any gains from a lower HbA1c target over a follow-up period of 3.5 to 5.6 years. Additionally, there is a possibility that **very aggressive glucose lowering in patients with established diabetes may confer a survival disadvantage**.

G. Recent meta-analyses incorporating the above trials have added additional information to this topic. The analyses by Turnbull et al. (39) and Kelly et al. (40) reached

similar conclusions, with pooled data showing a reduced risk of major cardiovascular events in the group with intensive glucose control compared with less aggressive control. However, in both cases, the risk reduction was small: a 9% risk reduction (HR 0.91, 95% CI 0.84 to 0.99) in the study of Turnbull and a relative risk of cardiovascular disease of 0.9 (95% CI 0.83 to 0.98) in the study of Kelly. Both concluded that cardiovascular mortality was unchanged between the two management strategies. Intensive glucose control was also highlighted as conferring at least a twofold risk for severe hypoglycemia in both papers. Both groups also found a small risk reduction regarding MI—a 15% reduction in fatal and nonfatal MI in the study of Turnbull and a 16% reduction of nonfatal MI risk in the study of Kelly. Turnbull et al. described a subgroup of patients who did not appear to benefit from more intensive control: individuals with a history of macrovascular disease existing prior to randomization.

Another meta-analysis, incorporating similar trials as the Turnbull and Kelly analyses, reached a slightly different conclusion. Ray et al. determined that intensive glucose lowering resulted in a significant reduction in nonfatal MI and in all coronary heart disease events. Cardiovascular mortality was not reported; all-cause mortality was equivalent in the pooled standard and intensive treatment groups (41).

H. The 2009 ACC/AHA Scientific Statement supports a goal HbA1c of ≤ 7%, with acknowledgment of the benefits of tight control in terms of microvascular disease, but recognizes the paucity of evidence for a cardiovascular benefit (42). Based on the currently available literature, individuals with diabetes cannot be confidently advised that stricter glucose control will reduce their likelihood of future cardiovascular events or mortality.

V. DIABETES PHARMACOTHERAPY

A. The spectrum of medications available to manage diabetes has expanded greatly over recent years. There has been increasing recognition that there may be significant differences between the cardiovascular impact of the various medications, even if the glycemic effects are equivalent.

1. Insulin is available in short-, medium-, and long-acting preparations, with synthetic human insulin and analogs of human insulin differing in their rates of absorption and durations of action. Mixtures of rapid short-acting and intermediate-acting insulin are also commonly used. Recombinant human insulin is synthesized using *Escherichia coli* bacteria, and subtle variations in the amino acid chain deter the insulin molecules from forming aggregates, thus creating a faster-onset, shorter-acting drug than regular insulin.

a. The different recombinant rapid-acting insulins—lispro, aspart, and glulisine—each have differing amino acid substitutions. All three can be injected subcutaneously to prevent postprandial glucose elevations, for rapid correction of elevated glucoses, and in insulin pumps. The onset of action is 15 minutes, with peak effect around 1 hour and a duration of action around 3 to 4 hours. An inhaled short-acting insulin was marketed briefly, but has now been withdrawn due to limited patient uptake.

b. Regular insulin is designated as a short-acting preparation. It has onset of action within 30 to 60 minutes, a peak time of 2 to 4 hours, and a duration of action around 6 to 8 hours. It can be used in intravenous infusions, as well as subcutaneously.

c. Neutral protamine Hagedorn (NPH) is an intermediate-acting insulin. Its time to onset is 1 to 3 hours, and the total duration of action is 12 to 16 hours. It can be injected either once daily at bedtime to lower fasting glucose levels (typically in individuals on oral hypoglycemics who are above A1c target) or as a twice-daily basal medication in combination with a shorter-acting prandial insulin. This latter approach is known as a basal-bolus regimen

and is widely used to achieve tight glucose control. In the basal-bolus regimen, a twice-daily intermediate-acting insulin, or a once-daily long-acting insulin, provides basal coverage and controls the fasting glucose levels. The three prandial insulin doses, administered just before mealtimes, cover the ingested carbohydrates and so limit postprandial glucose elevation. This is considered to be the most "physiologic" method of insulin administration, as it simulates the insulin-release patterns of the β-cells.

d. Glargine and detemir are the available long-acting agents, usually injected at night, and show minimal peaking. Glargine has a 24-hour profile of action, whereas detemir is more variable at 6 to 24 hours.

2. Insulin pumps are devices that can be programmed to release a continuous infusion of insulin into the subcutaneous tissue. An abdominal infusion site is the usual location, and the catheter should be changed every 2 to 3 days. These pumps are generally used in patients with T1DM and are most suited to knowledgeable and motivated individuals. They have been demonstrated to achieve greater success with target A1c levels and reduce the number of severe hypoglycemic episodes, compared with traditional subcutaneous insulin injections. **A newer innovation is the subcutaneous continuous glucose-monitoring system that detects glucose levels in the interstitium of subcutaneous tissue**. The real-time display of glucose levels can assist patients in anticipating insulin requirements and avoiding severe hypoglycemia. The currently marketed devices are each limited to a few days of continuous wear. Closed-loop systems that consist of both a subcutaneous continuous glucose sensor and an insulin pump are in development.

Insulin can cause weight gain and carries a risk of severe hypoglycemia. The hypoglycemic risk is increased in patients with renal and/or hepatic dysfunction, as the liver and kidneys are responsible for the majority of gluconeogenesis and glycogenolysis; in addition, insulin is renal excreted. The associated weight gain and hypoglycemia raised questions when the ACCORD trial revealed higher mortality in the intense therapy arm, where 77% of subjects were using insulin (vs. 55% in the standard care arm). The recent Euro Heart study also suggested harm related to insulin use. Insulin-treated patients with diabetes had an adjusted 1-year HR for mortality of 2.23 (95% CI 1.24 to 4.03, $p = 0.006$) and for cardiovascular events of 1.27 (95% CI 0.85 to 1.87, $p = 0.230$) compared with those taking oral hypoglycemic agents (predominantly sulfonylurea, metformin, or a combination of the two) (43). However, this study was nonrandomized and the choice to prescribe insulin was made by the treating physicians.

a. Metformin addresses glycemia by several mechanisms: it reduces hepatic gluconeogenesis by inhibiting glucose-6-phosphate dehydrogenase and works as a peripheral insulin sensitizer, with promotion of insulin-induced glucose movement into skeletal myocytes and adipocytes. As it does not stimulate insulin release, there is minimal hypoglycemic risk. This drug is considered first line in overweight patients with T2DM and is not associated with the weight gain that is encountered with insulin and the sulfonylureas. Metformin's insulin-sensitizing mechanisms have also found a role in the treatment of metabolic syndrome, polycystic ovarian syndrome, and nonalcoholic fatty liver disease, each of which is associated with insulin resistance. There is evidence for improvements in lipid profiles with metformin use. Metformin is contraindicated with impaired renal function (creatinine > 1.5 mg/dL in males and > 1.3 mg/dL in females is often quoted as the threshold) and also decompensated heart failure, where the risk of lactic acidosis may be elevated. Lactic acidosis, which can arise in the setting of reduced renal lactate clearance coupled with insufficient uptake of lactate into the liver because of gluconeogenesis inhibition, is considered to be rare. However, **it is standard of care to discontinue metformin**

during periods of renal impairment or inpatient heart failure treatment and for 24 hours before and 48 hours after injection of iodinated contrast agents. The majority of the reported side effects are gastrointestinal and can include diarrhea, nausea, early satiety, and abdominal pain.

b. **Sulfonylureas** are **insulin-stimulating oral agents**, with action on the adenosine triphosphate (ATP)-sensitive potassium channel found on the pancreatic β-cell. Binding of a sulfonylurea causes a decrease in potassium efflux through the K^+_{ATP} channel, inducing membrane depolarization that leads to calcium influx into the β-cell. Insulin release from secretory granules results. The main side effect is hypoglycemia; weight gain can also be a complication. Questions have also been raised regarding their potential to inhibit ischemic preconditioning via blockade of myocardial K^+_{ATP} channels. The commonly used second-generation sulfonylureas, such as glipizide, glimepiride, and glyburide (also known as glibenclamide outside the United States), are largely metabolized by the liver and excreted renally.

c. **Thiazolidinediones** are a newer class of drugs that have attracted much controversy with regard to their effects on the heart. The two agents developed in this class, **rosiglitazone and pioglitazone, act by increasing insulin sensitivity in target peripheral tissues**. This is achieved via activation of the peroxisome proliferator–activated receptor (PPAR)-γ nuclear receptor in myocytes and adipocytes, encouraging insulin-stimulated glucose transport into the cell. Pioglitazone also acts as a partial agonist of the PPAR-α receptor, which is believed to be the reason for increased HDL and decreased LDL and TGs observed with this drug.

Peripheral edema is a noted side effect; hence, this class of drugs should ***not*** be used in patients with NYHA class III–IV heart failure due to concerns for sodium and water retention and possible precipitation of heart failure decompensation. Weight gain, by expansion of subcutaneous adipose tissues, is also an associated complication.

There is some evidence, mostly using surrogate outcomes such as carotid intimal thickness and progression of coronary atherosclerosis by intravascular ultrasound, for a deterrent effect on atherosclerosis by pioglitazone in comparison with a sulfonylurea (44, 45). Analysis of a database including 16,390 clinical trial participants demonstrated that pioglitazone is associated with a significantly lower risk of death, MI, or stroke among a diverse population of patients with diabetes (46). However, the risk of heart failure was increased with pioglitazone, although without an associated increase in mortality. Conversely, rosiglitazone has been associated with an excess risk of MI and cardiovascular mortality in a meta-analysis (47). This led to the subsequent publication of the RECORD trial, which demonstrated overall noninferiority for a combination of metformin and sulfonylurea, but an increased risk of heart failure hospital admission or death with rosiglitazone (48).

(a) **Meglitinides**, such as repaglinide and nateglinide, are relatively short-acting oral insulin secretagogues. They are taken just prior to a meal and help to lower postprandial glucose levels. Due to their short duration of action, meglitinides are useful in the elderly and individuals with erratic eating habits.

(b) **Alpha-glucosidase inhibitors** such as acarbose and miglitol delay the absorption of complex carbohydrates via their action on the glycosidase enzymes in the brush border of the small intestine. They are generally used as an adjunctive therapy and can be useful in controlling postprandial glycemia. As described above, the STOP-NIDDM trial suggested a role for acarbose in reducing the progression of IGT to diabetes (11). The major side effects are flatulence and abdominal pain.

(c) **Amylin** is also an adjunctive agent and can be combined with prandial insulin therapy in T1DM or T2DM patients not meeting glucose targets. Pramlintide is a synthetic version of endogenous amylin, which is synthesized by β-cells and secreted with insulin in response to a carbohydrate load. The major effects appear to be inhibition of gastric emptying and suppression of glucagon release. Insulin doses should be reduced on initiation of pramlintide injections to avoid potential hypoglycemia. This agent may assist in reducing body weight.

(d) **Incretins** are a new class of agents for T2DM and include the GLP-1 and glucose-dependent insulinotropic peptide (GIP). The incretin hormones stimulate β-cell proliferation in animal models and are found at lower-than-normal levels in patients with T2DM. The active form of GLP-1 is the amide GLP-1(7-36), which is secreted by entero-endocrine L cells of the ileum and colon in response to a carbohydrate load. Exenatide is a synthetic GLP-1 analog that is subcutaneously injected twice daily. It works by potentiating insulin secretion, decreasing postprandial glucagon, delaying gastric emptying, and promoting weight loss. Liraglutide works in a manner similar to exenatide but has a longer half-life and is dosed once daily. Side effects include diarrhea and vomiting, and hypoglycemia is also a concern.

(e) **Dipeptidyl peptidase-4 (DPP-4) inhibitors** work by deterring the DPP-4-mediated degradation of GLP-1 and GIP into inactive metabolites. The first DPP-4 inhibitor to be marketed was the once-daily oral agent sitagliptin, with saxagliptin and vildagliptin (not approved in the United States) following since. There have been postmarketing concerns regarding pancreatitis and suggestions that inhibition of DPP-4 could promote carcinogenesis. DPP-4 inhibitors are weight neutral and carry a low risk of hypoglycemia; both liraglutide and exenatide have demonstrated the ability to reduce systolic blood pressure. Liraglutide also has a positive effect on the lipid profile and cardiovascular risk biomarkers.

Hence, the GLP-1 analogs and DPP-4 inhibitors have attracted significant recent attention regarding the possibility of favorable cardiovascular effects. GLP-1 receptors are known to exist on cardiomyocytes, and animal models of heart failure have shown positive responses to GLP-1. Improvements in left ventricular ejection fraction were reported in 10 patients who received a 72-hour GLP-1 infusion post-MI with successful primary angioplasty, when compared with 11 controls (49). Sokos et al. also reported significant improvements associated with a GLP-1 infusion in advanced heart failure patients (50). Of the 18 participants in NYHA class III–IV failure, 11 received a 10-week subcutaneous infusion with an escalating dose of GLP-1 and 7 received a placebo infusion. Significant improvements in the GLP-1 group were reported for several end points including left ventricular ejection fraction, oxygen consumption, the 6-minute walk test, quality of life, NYHA class, and B-type natriuretic peptide levels. However, neither of these pilot studies was randomized.

B. With the host of contrasting mechanisms described, it is clear that the various medications for diabetes cannot be expected to have equivalent effects on the cardiovascular system and future cardiovascular events, irrespective of any similarities in the degree of glucose lowering. The potentially negative cardiovascular effects of insulin and the sulfonylureas are of particular interest for further investigation. BARI-2D aimed to shed light on this uncertainty, but did not reveal a cardiovascular outcome difference between individuals randomized to a insulin provision therapy (insulin or sulfonylurea) versus insulin sensitization (metformin or thiazolidinedione) over a mean of

5.3 years (51). However, the extensive use of rosiglitazone and a relatively high crossover rate between the randomized groups confounded the interpretation of this trial.

C. It is hoped that the next generation of large clinical trials addressing the relationship between glycemic control and cardiovascular outcomes will be able to tease apart the relative effects of the major drug classes on the heart. This may require a shift in focus away from HbA1c. As described above, postprandial glucose may be a useful parameter to follow in future cohorts.

D. A related area of investigation has been the implementation of intensive glucose control regimens in the period immediately after an acute coronary syndrome.

1. The use of insulin in the setting of an acute MI was first described in the 1960s, with the goal of facilitating potassium flux in the ischemic myocardium. After decades of investigation, the combination of intravenous glucose, high-dose insulin, and potassium ("GIK" therapy) was concluded to offer no benefit in the setting of ST-segment elevation myocardial infarction (STEMI) and may have caused harm in some studies (52). Hence, this practice has been abandoned and should be distinguished from trials of intensive intravenous insulin therapy for tight glucose control post-MI.
2. The first DIGAMI study actually used a GIK protocol and infused insulin at 5 units/h with intravenous glucose to achieve glucose in the 126 to 198 mmol/dL range. Therefore, it was not a study of tight glucose control, although it has often been misinterpreted as such. The DIGAMI study did, however, raise interest in post-MI glucose control by suggesting that a 24-hour insulin-glucose infusion followed by intensive subcutaneous insulin in patients with diabetes could improve long-term survival post-MI (53). The mortality benefit seen at 1 year continued out to 3.5 years, with an absolute mortality reduction of 11%. The effect was most apparent in patients who had not previously received insulin treatment and who were at a low cardiovascular risk.
3. The subsequent DIGAMI-2 trial employed three acute MI glucose management strategies: acute insulin-glucose infusion followed by insulin-based long-term glucose control versus insulin-glucose infusion followed by standard glucose control versus routine metabolic management according to local practice (54). In the first two groups, the objective was to decrease the plasma glucose as rapidly as possible and maintain a level between 126 and 180 mg/dL. This trial did not reproduce the benefits seen in DIGAMI-1, with no differences seen in mortality or nonfatal re-infarctions between the three groups. As a result, guidelines currently recommend a more conservative target of < 180 mg/dL in the post-ACS phase.
4. This more lenient approach was supported by the NICE-SUGAR trial, which randomized 6,104 patients to intensive glucose control (target blood glucose range of 81 to 108 mg/dL) or conventional glucose control (target < 180 mg/dL) (55). The intensive group showed a higher odds ratio (OR) for death of 1.14 (95% CI 1.02 to 1.28; $p = 0.02$). This was despite the incidence of hypoglycemia in the intensive control group (6.8%) being the lowest of all the post-MI trials published.
5. HEART2D sought to test the approach of tight postprandial hyperglycemia control in patients enrolled within 21 days of a hospital admission for acute MI (56). It showed no difference between a prandial insulin therapy arm and a basal insulin arm over a mean follow-up of 963 days, but the study was hampered by a low event rate, short follow-up period, and only minimal differences in glycemia achieved between the two groups.

E. **Novel and future diabetes therapies** offer new potential strategies to pursue normalization of glycemia. Islet cell transplantation, delivered via a catheter into the portal vein, is currently under investigation. Whole pancreas transplantation is occasionally performed, usually in the setting of a patient requiring renal transplant who is already receiving immunosuppressive medications. T1DM is caused by T-cell–mediated β-cell destruction. There are preliminary animal data that autoreactive T cells may be removed from the circulation using stem cells transduced

to express major histocompatibility complex class II β chains. Stem cells are also a potential source for regeneration of pancreatic β-cells. However, significant challenges include preventing autoimmune destruction of regenerated β-cells and inducing physiologic insulin release in these cells.

VI. REVASCULARIZATION IN PATIENTS WITH DIABETES

A. The cardiovascular management of patients with diabetes incorporates not only careful consideration of medical regimens but also review of the available literature with regard to revascularization strategies. There have been many advances in evidence-based management of obstructive coronary lesions over recent decades, and many of the trials have identified strategies that confer particular benefit in individuals with diabetes.

1. **CABG versus PCI.** A series of landmark trials in patients with obstructive CAD have defined current practice with regard to the decision between CABG and PCI. The finding in 1997 that **the BARI subgroup with diabetes had a significant survival benefit in favor of CABG heralded the onset of specific coronary strategies for patients with diabetes**. The subgroup was not prespecified, but the survival benefit was considerable: in subjects receiving insulin or oral agents for diabetes (347 of the total cohort of 1,829), those randomized to CABG had a 80.6% 5-year survival, whereas balloon angioplasty was associated with 65.5% survival (57). This was in the interventional era prior to coronary stenting, and the explanation for the poor PCI outcomes in BARI subjects with diabetes is a presumed high rate of vessel restenosis. In addition, patients with diabetes tend to have more diffuse CAD, and lesions distant from the angioplasty site are left unprotected by a PCI strategy.
2. **CABG versus PCI with bare metal stents (BMSs) and glycoprotein IIb/IIIa inhibitors.** The widespread adoption of coronary stenting—at this stage with BMS—was successful in reducing restenosis rates. Sustained angiographic coronary patency also correlated with superior survival outcomes, symptom scores, and improved regional left ventricular systolic function. The randomized Arterial Revascularization Therapy Study (ARTS) of CABG versus PCI in multivessel disease showed equivalence of major outcomes for CABG and PCI strategies, with the caveat that the incidence of repeat revascularization was higher in the PCI group (58).

   This trial was also notable for its diabetes subgroup results; **there was a benefit in terms of 1-year repeat revascularization and major cardiovascular events in patients with diabetes who underwent CABG, as compared with stenting**. Other studies of this era, including the Stent or Surgery (SOS) trial published in 2002 (59), demonstrated superiority of CABG over PCI in patients with multivessel disease in general, but these were performed prior to routine use of thienopyridines and glycoprotein IIb/IIIa inhibitors. The addition of a platelet glycoprotein IIb/IIIa inhibitor appears to be particularly beneficial for patients with diabetes presenting with an ACS. A meta-analysis by Roffi et al. involving 6,458 patients with diabetes and non–ST-segment elevation ACS showed a significant reduction in the aggregate 30-day mortality (OR 0.74, 95% CI 0.59 to 0.92) with use of a glycoprotein IIb/IIIa inhibitor (60). Although not based on a randomized assessment, this survival advantage appeared to be particularly marked in patients who underwent PCI during the hospitalization.
3. **CABG versus drug-eluting stents (DESs).** DESs offer a further deterrent to vessel restenosis, although at the expense of an early in-stent thrombosis risk, particularly if antiplatelet medications are insufficient or ineffective. These stents deliver an antiproliferative drug locally to inhibit neointimal hyperplasia and improve target lesion patency. They have been clearly demonstrated to reduce angiographic restenosis rates, although there has been less of an impact on cardiovascular outcomes and mortality.

A 2006 meta-analysis of 12 studies by Kumbhani et al., including 1,902 patients with diabetes treated with either a DES ($n = 1,089$) or a BMS ($n = 813$), demonstrated an association between DESs and significant risk reductions in major adverse cardiac events (MACE), target lesion revascularization, and in-stent restenosis (with the reductions in MACE being primarily driven by the significant reductions in revascularization) (61). Also of note was an analysis comparing the relative risk of in-segment restenosis between the two types of DESs, which found a nonsignificant benefit favoring sirolimus-eluting stents versus paclitaxel-eluting stents (PESs).

Although there appears to be a dramatic restenosis reduction with the use of DESs compared with BMSs, patients with diabetes still encounter a higher rate of cardiovascular events post-PCI than those without diabetes. The comparative effectiveness of PESs or sirolimus-eluting stents in diabetes remains controversial. Increases in late stent thrombosis or restenosis, which are particularly likely in patients with diabetes and renal failure or complex lesions, need to be considered.

The SYNTAX trial investigated the strategies of PCI with PES versus CABG in patients with triple-vessel or left main disease; approximately 26% of SYNTAX participants had diabetes (62). An evaluation of the 452 SYNTAX subjects with diabetes, 40% of whom received insulin, showed that mortality was significantly higher among subjects with diabetes compared with those without, regardless of the revascularization strategy (63). At 1 year, the only outcome difference between PCI and CABG in patients with diabetes was the excess of repeat revascularization in the PCI arm. **Patients with diabetes had significantly increased repeat revascularization rates compared with those without diabetes when treated with PES, but not after CABG**. The CARDia trial was underpowered, but reached a similar conclusion. Stroke was nonsignificantly higher in the SYNTAX CABG arm. Further information on the relative merits of CABG and PCI in patients with diabetes and multivessel coronary disease is expected from the ongoing FREEDOM trial.

4. **Current antiplatelet strategies.** Antiplatelet requirements post-PCI do not differ between patients with or without diabetes. However, given the higher risks of target lesion revascularization and in-stent restenosis in those with diabetes, it can be expected that patients with diabetes have the most to lose from insufficient or ineffective antiplatelet therapy. Current recommendations are that all patients with coronary stents remain on daily aspirin lifelong. A thienopyridine should be taken for a very minimum of a month post-BMS placement; patients who receive a DES should take a thienopyridine uninterrupted for at least 12 months. The recent introduction of prasugrel has relevance to individuals with diabetes. TRITON–TIMI 38 enrolled intermediate-risk/high-risk ACS patients and STEMI patients who underwent PCI (64). Participants were randomized to prasugrel 60 mg load and 10 mg daily maintenance versus 300 mg load and 75 mg daily clopidogrel. The primary composite end point was significantly reduced with prasugrel in patients without diabetes (HR 0.86) and even more significantly reduced in those with diabetes (HR 0.70).
5. **CABG outcomes. Bypass conduit attrition rates are known to be higher in patients with diabetes**. As in patients without diabetes, the use of the internal mammary arteries (IMAs) offers higher long-term patency (in the region of 90% at 10 years) compared with reversed saphenous veins (long-term patency varying between 40% and 75%). Therefore, IMAs are particularly attractive in patients with diabetes, although the practice of using bilateral IMA grafts is controversial due to the potential for sternal wound infections. In addition to wound infections, patients with diabetes have an elevated risk of perioperative stroke with CABG surgery, with an OR of 1.4 (95% CI 1.2 to 1.8) for stroke (65). PCI does not carry an additional stroke risk for patients with diabetes and, therefore, may be the preferable option in patients with diabetes who have multivessel disease

and a preserved left ventricular ejection fraction and coronary lesions amenable to stenting. There are various measures such as preoperative noninvasive carotid artery assessment and modifications of the cross-clamp technique that can help to minimize peri-CABG stroke rates in high-risk patients.

6. **Revascularization versus optimal medical therapy.** The COURAGE trial raised questions regarding the relative merits of a purely medical versus medical and PCI strategy in patients with obstructive CAD and stable symptoms (66). This somewhat controversial study concluded that PCI added to optimal medical therapy did not reduce the primary composite end point of death and nonfatal MI or reduce major cardiovascular events over a 2.5- to 7.0-year period. A third of the participants had diabetes. The 1,605 patients with diabetes enrolled in the PCI versus optimal medical therapy stratum of BARI-2D did not show any difference in cardiovascular outcomes (51). However, both of these trials randomized patients after an initial angiogram that defined anatomy, and the decision to enroll in the PCI arm of BARI-2D (as opposed to the CABG arm) was made once anatomy was known and at the discretion of the investigators.
7. **Screening asymptomatic patients with diabetes for CAD.** Given the elevated risk of CAD in patients with diabetes, investigators have attempted to determine whether identification of asymptomatic CAD can improve future outcomes for patients with diabetes. The Detection of Ischemia in Asymptomatic Diabetes (DIAD) study used a nuclear cardiac stress imaging protocol to identify patients likely to have CAD (67). At 5 years, there was no difference in nonfatal MI or mortality between the nuclear screening and standard care groups. However, the screening arm was notable for a very low rate of significant ischemia detection, and there was a very successful protocol of optimal medication therapy among trial participants.
8. **Screening for diabetes in patients with cardiovascular disease or risk factors.** Given the degree of excess cardiac morbidity and mortality attributable to diabetes, and the proposed early window for tight glucose control with potential to impact on later cardiovascular risk, there is an argument for asymptomatic screening of high-risk patients for diabetes. **With the ease of diagnosis by HbA1c criteria and long asymptomatic prediabetes phase, T2DM meets WHO thresholds for a condition where screening may be appropriate**. However, it remains unproven as to whether early identification and aggressive management of diabetes has the ability to attenuate future cardiovascular risk. ADDITION-Europe sought to clarify this question with a cluster-randomized trial that assigned subjects to standard care versus an intense multifactorial management protocol (68). This study was not able to demonstrate a significant cardiovascular outcome benefit for early detection and management of diabetes at 5.3 years and was hampered by a low event rate and a smaller-than-expected difference in risk factor management between the two groups.

CHAPTER 46

Jun-Yang Lou

Heart Disease in Women

I. INTRODUCTION. Cardiovascular disease (CVD) is by far the leading cause of death of women in the United States and most developed countries, accounting for almost 39% of all female deaths in the United States. In 2007, CVD caused 421,918 deaths in women in the United States, approximately 1 per minute, **more than those claimed by cancer, chronic lower respiratory disease, Alzheimer disease, and accidents combined**. Despite aggressive campaigns by the American Heart Association (AHA) and other organizations, only 54% of the women surveyed in 2009 spontaneously listed coronary heart disease (CHD) as a woman's leading cause of death, and only 13% of the women surveyed identified CHD as a risk for them personally. Minority women are even less aware of their cardiovascular (CV) risk, which is higher than for age-matched white women.

Some important gender-related differences exist in the presentation and outcome of CVD. In a national registry of over 300,000 patients (40% women) admitted with acute myocardial infarction (MI) between 1994 and 1998, female patients were found to be older compared with males (approximately 72 years vs. 66 years, respectively). Women also had higher in-hospital mortality compared with men (17% vs. 12%). Risk of death is particularly high in younger women, more than twice that of men in the under-50 age group, and also in women who presented with ST-elevation myocardial infarction (STEMI). These differences highlight an urgent need to better understand and treat heart diseases in women. This chapter summarizes current understanding of the gender-specific features of CVD based on large-scale clinical trials and existing and emerging molecular science.

II. GENDER DIFFERENCES IN PATHOPHYSIOLOGY. Briefly, coronary artery disease (CAD) begins with **nascent atheroma**, the coalescence of small lipoprotein particles within the arterial intima. Over time, these lipoprotein particles become oxidized, inducing local cytokine elaboration. These inflammatory cytokines cause the increased expression of adhesion molecules for leukocytes, leading to leukocyte attraction and migration into the intimal layer. Blood monocytes become macrophages upon entering the intima and express scavenger receptors on their surface, owing to their interaction with certain cytokines present locally. These scavenger receptors promote the uptake of modified lipoprotein particles, leading to the formation of **foam cells**. Foam cells further elaborate inflammatory and attractant cytokines and other effector molecules. In response, smooth muscle cells migrate into the intima from the media, where they proliferate and form fatty streaks. Smooth muscle cell proliferation and extracellular matrix accumulation lead to the progression from a **fatty streak** to a **fibrofatty plaque**. Later stages are characterized by calcification and fibrosis, occasionally with smooth muscle cell death. This creates an acellular fibrous cap surrounding a lipid-rich core.

The process of atherosclerosis progresses slowly, and patients often remain unaware and asymptomatic for many years. This is likely attributable to the capacity of the arteries to remodel—expanding outwardly as the intima expands, thereby preventing plaque encroachment on the lumen of the vessel. However, at some point the plaque

burden exceeds the ability of the vessel to remodel, and narrowing of the lumen begins. Eventually, if unimpeded, atherosclerosis will progress until the degree of luminal narrowing impedes blood flow. Initially, this luminal narrowing is apparent mostly under the conditions of stress, where arterial oxygen supply is unable to meet demand. Once this occurs, the patient begins to develop symptoms, typically stable angina.

In some cases, however, the first manifestation of the underlying CAD is MI, unstable angina, or sudden death. In these instances, the underlying stenosis is usually < 50% of the lumen diameter. The inciting event leading to symptoms in these cases is either physical disruption of the fibrous cap of the plaque or superficial erosion of the intima. Either setting exposes the underlying lipid-rich core to blood components and initiates thrombosis (see Chapters 1 and 2 for more detailed discussions). Women, **especially younger women, are twice as likely to have plaque erosion as the underlying cause of MI**, whereas men and older women more often have plaque rupture. Compared to men, whose plaques tend to be more dense fibrous, women also tend to have more cellular fibrous plaques.

There appears to be other gender-based differences in the atherosclerotic process. Hormones have also been proven to influence many of the underlying pathophysiologic processes, including vasoreactivity, thrombosis and inflammation. Women have smaller coronary arteries than men and, interestingly, women taking androgens have much larger coronary arteries than their age-matched controls. For years it was noted that premenopausal women appeared to be protected from CAD and estrogen emerged as the most likely reason. A recent animal study suggests that estrogen appears to decrease oxidative stress via upregulation of the production of prostacyclin PGI_2, a molecule known to retard the progression of atherosclerosis. The full spectrum of sex hormone effects on the heart and vascular system has yet to be fully determined. In addition, there have been genetic links to the development of CAD that are noted to vary according to gender, with different single-nucleotide polymorphisms noted in men and others in women. There are also differences in terms of endothelial function and hemostasis (women have higher levels of fibrinogen and factor VII). Some of these or other mechanisms may eventually be identified as the reason for gender differences in the development and progression of CAD.

In recent years, microvascular dysfunction has been postulated as the underlying process leading to symptoms of CHD in some women. It is postulated that estrogen withdrawal in perimenopausal and postmenopausal women leads to impaired vasodilatation and/or enhanced vasoconstriction. This hypothesis stems from the diagnosis of **cardiac syndrome X, in which patients, predominantly postmenopausal women, exhibit symptoms of typical angina pectoris with transient abnormal** electrocardiogram (**ECG**) **and/or stress perfusion studies**, yet most have minimal angiographic evidence of CAD when undergoing left heart catheterization (LHC). Further studies are needed to better define the populations at risk for microvascular dysfunction and determine potential therapeutic interventions.

Stress (Takotsubo) cardiomyopathy is another novel disease entity affecting predominantly postmenopausal women, accounting for over 80% of cases. Alternatively known as apical ballooning syndrome or broken heart syndrome, stress cardiomyopathy is diagnosed when patients, often in the setting of severe emotional distress or physical trauma, present with chest pain, anterior ST elevations, mildly abnormal cardiac biomarkers, and characteristic appearance of an akinetic, ballooning apex on echocardiography or left ventricular (LV) ventriculogram. Angiography often reveals normal-appearing coronary vessels. The etiology of stress cardiomyopathy and the reason behind such strong female predilection are unclear. Catecholamine surge with stress has been implicated in a number of patient cohorts with this cardiomyopathy. The prognosis of stress cardiomyopathy is quite good, as the majority of patients regain systolic function within 6 months.

III. GENDER DIFFERENCES IN RISK FACTORS

A. Diabetes mellitus. Diabetes affects more women than men after the age of 60. It is associated with a higher incremental risk for CAD (two to four times the risk of women

without diabetes) and drastically increases the mortality of MI in women, much more so than in men. Type 2 diabetes is associated with other components of the metabolic syndrome, all of which increase risk for CAD. Diabetes is also strongly associated with the development of heart failure, with or without preserved ejection fraction.

B. Hypertension (HTN). More than 73% of women aged 65 to 74 years have HTN. The risk of developing HTN increases for women if they are 20 pounds or more overweight, have a family history of HTN, or have reached menopause. Risk for CVD related to HTN rises steeply with age, although most studies show that treatment attenuates this risk.

C. Hyperlipidemia. Lipid fractions in women are affected by their menopausal status. Premenopausal women have lower low-density-lipoprotein cholesterol (LDL-C) levels and higher high-density-lipoprotein cholesterol (HDL-C) levels than age-matched men. With aging, LDL-C increases and HDL-C decreases, causing the risk of CAD to increase. Total cholesterol and LDL-C are less predictive in women, unlike HDL-C, which is inversely associated with the risk. Non–HDL-C and total cholesterol to HDL-C ratio are more predictive in women than in men. In addition, triglycerides are a more potent independent predictor of CAD, especially in older women.

D. Cigarette smoking. This is the single most preventable risk factor. Smoking leads to more CVD deaths than any other risk factor, likely owing to its effects of increasing inflammation, thrombosis, and oxidation of LDL-C. Smoking also has an antiestrogen effect, inducing unfavorable changes in lipid levels. There is a sixfold to ninefold increased risk of MI in female smokers compared with age-matched nonsmokers; in fact, the risk from smoking is equivalent to the risk of weighing about 42 kg more than a nonsmoking woman. However, with smoking cessation, risk is cut in half after 1 year without smoking and eventually declines back to baseline nonsmoker's risk.

E. Obesity and metabolic syndrome. More than 30% of American women are obese, and this number continues to climb. In women, obesity and body fat distribution (i.e., abdominal location) are independent risk factors for CAD. As shown by an examination of a cohort of 115,195 women from the Nurses' Health Study, risk of death from CVD increased with increasing body mass index (BMI). Abdominal fat accumulation leads to the development of other components of the metabolic syndrome, such as HTN, diabetes, and hypertriglyceridemia. Obesity is also associated with elevated levels of C-reactive protein (CRP), more so in women.

Women with the metabolic syndrome more often have subclinical CAD than men. A substudy from the National Heart, Lung, and Blood Institute-sponsored WISE (Women's Ischemia Syndrome Evaluation) study revealed that women with the metabolic syndrome have twice the risk for CHD-related events compared with age-matched women without the metabolic syndrome. The metabolic syndrome is defined by the National Cholesterol Education Program Adult Treatment Panel-III in women as the presence of three or more of the following components:

(1) Waist circumference > 35"
(2) Fasting triglycerides > 150 mg/dL
(3) HDL-C < 50 mg/dL
(4) HTN (systolic blood pressure ≥ 130 mm Hg, diastolic blood pressure ≥ 85 mm Hg, or use of antihypertensive drug therapy)
(5) Fasting glucose ≥ 110 mg/dL

F. Estrogen/menopause. Postmenopausal women have more CVD risk factors, such as obesity, HTN, and hyperlipidemia, likely owing to the changing hormonal environment (estrogen levels are one-tenth the premenopausal level). The predominant source of estrogen changes from estradiol in the premenopausal state to the much weaker hormone estrone (produced by the conversion of androgens in peripheral adipose tissue) during menopause. Animal studies have shown that estrogen can have favorable CV effects, reducing cellular hypertrophy, enhancing vessel wall elasticity, and providing antioxidative and anti-inflammatory actions.

As part of the WISE study results, endogenous estrogen deficiency in young women was shown to be a strong risk factor for CHD, with a 7.4-fold increased risk. Because of the protection from CAD afforded for premenopausal women, there was early enthusiasm for the use of hormone replacement therapy (HRT) to prevent CVD in postmenopausal women, sparked by data from observational studies. However, multiple randomized, placebo-controlled trials over recent years have shown evidence of increased risk for CVD with HRT, such that it is no longer recommended for primary or secondary prevention of CVD (see Section **VI.F**).

G. Physical inactivity. As women age, they become less physically active than their male counterparts. This contributes to weight gain and predisposes to the development of diabetes and HTN. In addition, with the cessation of estrogen production with menopause, there is increased abdominal fat deposition, further predisposing to CAD. There is a strong inverse association between the activity level and incidence of CV events (see Table 46.2).

H. Novel risk factors. It has been increasingly realized that the traditional risk factors underestimate CHD risk in women. For this and other reasons, research has been focused on identifying other novel biomarkers that can better define a person's risk. Multiple biomarkers have been investigated to various degrees (e.g., high-sensitivity C-reactive protein [hsCRP], brain natriuretic peptide, and fibrinogen), but the greatest promise appears to be with hsCRP. As part of the Women's Health Study, over 27,000 healthy American women had their CRP and LDL-C levels measured. The women were then followed for a mean of 8 years for the occurrence of the primary end point (MI, ischemic stroke, coronary revascularization, or death from CVD). Although minimally correlated with each other, both CRP and LDL-C levels had strong linear relationships with CVD events, with CRP being the stronger predictor. Each biomarker tended to identify different high-risk groups, but better prognostic values were obtained when both were used together. These data suggest that CRP shows promise when added to traditional risk factors for prediction of long-term risk.

IV. GENDER DIFFERENCES IN CLINICAL MANIFESTATIONS.

Women often present differently than men, potentially because of differences in underlying pathophysiology. This is particularly true for diabetic women. Women usually present at an older age, usually 5 to 10 years later than men, and have more comorbidities on presentation than men do. As such, once the diagnosis of CAD is made, women are at higher risk for adverse outcomes.

A. Like men, women can present with typical symptoms of angina, such as substernal **chest pain** and **dyspnea on exertion** that is relieved by rest. These symptoms more often occur in older women, who present more similarly to men.

B. Women can also present with **atypical chest pain**; **shortness of breath**; **neck, shoulder, or arm pain**; **diaphoresis**; and **nausea/vomiting**.

C. Women are more likely to have subtle symptoms that require detailed history-taking to elicit, such as **chest "pressure or tightness," lightheadedness, palpitations, or fatigue**. Women most often have symptoms that occur at rest, wake them from sleep, or occur in times of psychological stress.

D. Women more often present acutely without preexisting prodromes of symptoms or with **sudden cardiac death**.

V. GENDER DIFFERENCES IN ASSESSMENT

A. Exercise electrocardiography. Exercise electrocardiography, the most frequently employed diagnostic modality, is useful only in women with normal baseline ECGs and with the ability to undergo moderate or high levels of exercise (generally on the treadmill). An abnormality is identified if there is ≥1 mm of ST-segment depression or elevation. Generally, exercise ECG has lower sensitivity and specificity than other modalities, and this is even more prominent in women (sensitivity and specificity

60% to 70% in women vs. 80% in men). This difference is not well understood, but it has been attributed to several factors, such as lower overall prevalence of CAD in women or more submaximal stress tests, owing to the inability of women to exercise to sufficient levels to produce a diagnostic test. If women are unable to achieve at least five metabolic equivalents (METS), studies have shown that they are at increased risk for future CV events.

B. Stress echocardiography (transthoracic echocardiography [TTE]). Stress TTE tends to have higher specificity and lower sensitivity than stress perfusion imaging, as wall motion abnormalities occur later than perfusion abnormalities. However, stress TTE has the advantages of eliminating radiation exposure, decreasing cost, and providing the ability to assess LV function and cardiac structures. It has been shown to be a cost-effective initial strategy for determining CV risk in patients at intermediate risk as compared with stress electrocardiography, and we now use it as a first-line diagnostic test for CAD in women.

C. Stress myocardial perfusion scan. Because of the limited sensitivity and specificity of exercise ECG in women, other modalities are frequently employed to assess the risk of CAD. The most frequently used test is the single-photon emission computed tomography (SPECT) scan, a radionuclide-based technique. Because alterations in myocardial perfusion generally occur earlier than electrocardiographic changes or wall motion abnormalities, this test is more sensitive than exercise ECG or echocardiography for estimating risk in either gender. For those individuals unable to exercise or attain target heart rates, adenosine or dipyridamole can be used as a pharmacologic stress agent. To increase specificity, the higher energy isotopes (technetium 99m) are recommended in women to reduce the soft tissue attenuation artifacts (influenced by both breast tissue and obesity) that tend to occur anteriorly and laterally. Other limitations of SPECT can be critical in women. Because women have smaller hearts, the limitations in spatial resolution of SPECT can lead to small areas of hypoperfusion being missed.

D. Magnetic resonance imaging (MRI). Although not as commonly used, this is an emerging modality owing to its ability to evaluate for subendocardial ischemia, precisely assess LV function and mass, and evaluate the anatomy of the myocardium and vasculature. MRI provides the best spatial and temporal resolution, which is thought to be especially helpful when imaging women. Other benefits include the ability to detect ischemia by identifying altered metabolism. This is achieved by magnetic resonance spectroscopy, which can detect alterations in high-energy phosphates and identify these areas of altered metabolism. Areas of altered metabolism have been shown in reports from the WISE study to be indicative of microvascular dysfunction, as women with nonobstructive CAD assessed by LHC have altered high-energy phosphate ratios indicative of ischemia identified by spectroscopy.

E. Coronary angiography. Diagnostic coronary angiography is the gold standard for diagnosing CAD in both men and women. When evaluated by LHC, however, women more often have minimal to no obstructive CAD. For reasons not fully elucidated, women tend to experience vascular complications such as bleeding and renal failure related to diagnostic LHC more frequently than men do. The occurrence of a complication is thought to be related to older age at the time of presentation, smaller body size, smaller vessel size, and higher prevalence of diabetes. A transradial approach to diagnostic and interventional coronary procedures has been shown to be safe and lead to less bleeding complications than transfemoral catheterizations in both men and women and thus might be considered the primary catheterization approach in women.

VI. GENDER DIFFERENCES IN THERAPIES. Most CVD in women, as in men, can be prevented if risk factor modification occurs early and aggressively. Until recently, most of the clinical trial data, on which the guidelines for prevention and treatment of both genders are based, were derived from trials conducted largely in men. This information

had been extrapolated to women because gender-specific trial data were lacking. Because of this uncertainty, more recent clinical trials have offered insights into gender-specific results, allowing for evidence-based guidelines for disease prevention and treatment in women. However, with only a few exceptions, the guidelines are the same for both men and women. The gender-specific results are highlighted here; for a full discussion, please see appropriate sections of previous chapters.

A. Aspirin. Aspirin (ASA) is the principal antiplatelet agent in patients with CAD. Its benefit in secondary prevention, as well as in acute coronary syndrome (ACS), STEMI, and after revascularization (coronary artery bypass grafting or percutaneous coronary intervention [PCI]), is well known and discussed elsewhere. However, there are very few gender-specific data in these instances, so most recommendations are extrapolated from trials conducted largely in men.

The role of ASA in primary prevention of CAD in women is better defined. Early data suggested that ASA may be protective as primary prevention for future CVD events in women, as it is in men. However, as part of the Women's Health Study, 39,876 healthy women older than age 45 were randomized to either ASA 100 mg on alternate days or placebo, and they were followed for the incidence of CV events (nonfatal MI, nonfatal stroke, or CV death) over 10 years. **Despite a 24% reduction in ischemic stroke, ASA had no benefit over placebo in reducing MI or CV death.** However, ASA did appear protective as primary prevention in those women aged 65 years or older, as it significantly decreased the risk of both MI and stroke in this age group. There was also an increased risk of bleeding observed, which highlights the need for an individualized approach to the use of ASA as primary prevention in older women. **Using "low-dose aspirin", i.e., 81 or 75 mg daily rather than the "full dose" of 325 mg daily, in women might confer effective CV protection without excessive bleeding risk.**

B. Thienopyridines. For two decades, the most commonly used agents in this class are clopidogrel and ticlopidine. The use of ticlopidine has decreased significantly with evidence of adverse effects, including neutropenia and thrombotic thrombocytopenic purpura. These agents have proven beneficial, when given with ASA, to reduce the rate of stent thrombosis after PCI. Clopidogrel has also shown benefit in secondary prevention of CAD, ACS, and STEMI (discussed in detail elsewhere). Few of the clinical trials using clopidogrel have given gender-specific data, but there are some data available for specific settings.

In the substudy of the Clopidogrel in Unstable angina to prevent Recurrent Events (CURE) trial, in which the patients received PCI (PCI-CURE), 2,658 patients with non–ST-segment elevation ACS undergoing PCI were randomly assigned to aspirin plus clopidogrel or placebo for 9 months. Of the study population, 30.2% were women. Clopidogrel plus aspirin long-term therapy improved outcomes in those patients who received PCI. This was more significant in men, but a definite trend toward benefit in women was evident as well. Similar results were seen for women in the Clopidogrel for the Reduction of Events During Observation (CREDO) trial, where 29% of the 2,116 patients were women. The CREDO trial showed benefit of post-PCI therapy with ASA and clopidogrel out to 1 year of therapy, again with a trend toward benefit in women. CREDO trial also revealed, by subgroup analysis, equally beneficial effects of a loading dose of clopidogrel in men and women.

Prasugrel is the most recent addition to the class of oral antiplatelet agents. Pharmacokinetic studies have shown that prasugrel achieves faster onset and greater extent of platelet inhibition compared with clopidogrel. It was FDA approved for patients with ACS undergoing PCI in 2009. In the Trial to Assess Improvements in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel—Thrombolysis in Myocardial Infarction 38 (TRITON-TIMI 38), prasugrel had lower primary end points (CV death, nonfatal MI, or nonfatal stroke) than clopidogrel in 13,608 patients (one-fourth of whom were women) with moderate- to high-risk ACS with

scheduled PCI (9.9% vs. 12.1%). However, the prasugrel group did have higher rates of bleeding particularly in patients with history of stroke or transient ischemic attack, patients aged 75 years or older, or patients weighing less than 60 kg. These data are especially important for women, as there was slightly less observed benefit with prasugrel therapy in women—this difference is likely related to increased risk of bleeding of antiplatelet use of any kind in woman, as shown by a recent post hoc analysis of the TRITON-TIMI 38 data.

C. Statins. Prior to the last several years, almost 20,000 women participated in clinical trials of statin use, only about one-fourth of overall participants. Two exceptions to this were the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER) trial (50% women) and the lipid-lowering therapy arm of the Antihypertensive and Lipid-Lowering treatment to prevent Heart Attack Trial (ALLHAT-LLT), which had 49% female participation. ALLHAT-LLT, a primary prevention trial, did not release gender-specific results; PROSPER, having patients with history of or at risk for CVD, did not show a statistically significant benefit in women.

Otherwise, the other major primary and secondary prevention trials of statin therapy have shown similar benefit with statin therapy on reduction of CV events in men and women. The largest number of women enrolled to date in a statin trial was the Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER) trial. With over 17,000 patients enrolled (38% of them women), this trial demonstrated encouraging evidence for the benefit of statin therapy in decreasing vascular events in both women and men with "normal" serum LDL-C and elevated serum CRP levels, with a ~45% reduction in combined end point of MI, stroke, or death from CV causes. In the Treating to New Targets (TNT) trial, patients who were given intensive lipid control treatment with higher dose of atorvastatin (80 mg) were shown to have a significantly reduced primary end point of a first major CV event (death from CHD, nonfatal MI, resuscitation after cardiac arrest, or fatal or nonfatal stroke) over those on lower dose therapy (atorvastatin 10 mg). Even more encouraging was that this benefit also extended to women. In women (19% of total population) from the TNT trial, the relative and absolute reductions in the primary end point were 27% and 2.7%, respectively; this was actually better than those observed in men, who had 21% and 2.2% reduction, respectively.

D. β-Blockers. There are no gender-specific data for the use of β-blockers in women for primary and secondary prevention, as previous studies have included insignificant numbers of women. However, a meta-analysis of 5,474 patients (1,121 women) enrolled in five randomized trials revealed similar reductions in CV death in men and women with metoprolol.

E. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs). With respect to the use of ACE inhibitors in women with LV dysfunction, the data are lacking, because trials have included very few women. Several trials have examined ACE inhibitors in primary and secondary prevention of CV events in patients without LV dysfunction, with conflicting results irrespective of gender. The Heart Outcomes Prevention Evaluation (HOPE) study showed that ACE inhibitors were associated with a mortality reduction in high-risk women that was similar to that in men. The EURopean trial On reduction of cardiac events with Perindopril in stable coronary Artery disease (EUROPA) could not confirm these beneficial findings in women, as the trial included only 14.5% women, but it did show benefit in men. To date, it appears that data for ACE inhibitors in women are not as favorable as for men; however, this needs to be further delineated.

In terms of ARBs for therapy after MI, only two trials have been reported—VALsartan in Acute myocardial iNfarcTion (VALIANT) and OPtimal Trial In Myocardial Infarction with Angiotensin II Antagonist Losartan (OPTIMAAL). Neither of these reported gender-specific data.

F. Hormone replacement therapy. Despite beneficial evidence from previous observational studies, recent data from randomized controlled trials have shown no benefit of HRT in postmenopausal women for preventing CV events. The first of these randomized trials was the Heart and Estrogen/progestin Replacement Study (HERS). In this study of secondary prevention, 2,763 postmenopausal women with CAD were randomized to either 0.625 mg of conjugated equine estrogen plus 2.5 mg of medroxyprogesterone acetate or placebo daily. After an average 4-year follow-up, there was no significant difference in the primary outcome of nonfatal MI or CHD death between the groups. Of interest, however, was the fact that the greatest numbers of CV events were noted within the first year in the HRT group. Not surprisingly, the HRT group had a greater incidence of venous thromboembolism and gallbladder disease.

Because of the high number of CV events in the first year, the investigators thought that beneficial effects of HRT might be observed after time, as it appeared that HRT became more protective by 4 to 5 years of follow-up in the HERS population. With this in mind, the HERS II study followed 2,321 of the original HERS patients, the majority of whom stayed on their original treatment in an open-label format, for an average of 6.8 years. After the longer follow-up, there was still no difference in nonfatal MI or CHD death between the groups.

To delineate the role of HRT in primary prevention of CV events, the Women's Health Initiative randomized 16,608 healthy, postmenopausal women to the same estrogen–progestin combination used in HERS or placebo. The primary end points were the same, nonfatal MI or death due to CHD. After a mean 5.2-year follow-up, the trial was stopped by the data and safety monitoring board due to untoward risks in the treatment arm. Estrogen and progestin therapy was associated with an increased risk for CV events, most impressively at 1 year. Despite some favorable effects on lipids, **HRT should not be recommended for either the primary or the secondary prevention of CVD in postmenopausal women**.

G. Lifestyle modification. The good news for women is that initiating lifestyle modifications can reduce CV risk by reducing the risk of developing diabetes. As part of the Diabetes Prevention Program Research Group, 3,234 patients (68% women) with impaired glucose tolerance were randomized to placebo, metformin (850 mg twice daily), or lifestyle modification (goal 7% weight loss and at least 150 minutes of physical activity per week). After almost 3 years of follow-up, the lifestyle modification group had a 58% reduction in the incidence of diabetes compared with 31% in the group with metformin. This translates to a decreased risk of CVD.

H. Folic acid and antioxidants. Despite previous recommendations to lower homocysteine levels with folic acid and vitamin B supplementation, there is now evidence to discourage this practice. Three randomized trials—the Norwegian Vitamin (NORVIT) study, the HOPE-2 trial, and Women's Antioxidant and Folic Acid Cardiovascular Study (WAFACS)—showed no benefit in reducing CV events. The NORVIT study included both men and women post-MI and randomized the groups to one of four treatments: folic acid, vitamin B_{12}, and vitamin B_6; folic acid and vitamin B_{12}; vitamin B_6 alone; or placebo. Despite lowering of homocysteine levels, the treatment groups had no advantage in terms of reductions in the primary end point of recurrent MI, stroke, or sudden death attributed to CAD. In fact, the group that received all three therapies had a trend toward increased risk. Similar results were seen in the HOPE-2 trial. Therefore, these therapies should not be recommended. In addition, data from the Women's Health Study do not support the use of vitamin E in the primary prevention of CV events.

VII. EVIDENCE-BASED GUIDELINES FOR HEART DISEASE PREVENTION IN WOMEN.

The American College of Cardiology/American Heart Association (ACC/AHA) guidelines emphasize the importance of recognizing the wide-ranging spectrum of CV disease in women. In general, a woman aged 20 years or older is first classified as at high risk, at

risk, or at optimal risk based on the criteria in Table 46.1. Several factors should be evaluated, such as medical history, lifestyle, family history of premature CAD, Framingham risk score, and other genetic conditions, before decision regarding the aggressiveness of preventive therapy is finalized.

TABLE 46.1 Risk Classification of Cardiovascular Disease in Women

High risk	At risk	Optimal risk
• Known CAD	• **Subclinical atherosclerosis (e.g., coronary calcification, carotid plaque, or thickened intima-media)**	• Fasting blood glucose < 100 mg/dL (untreated)
• Cerebrovascular disease	• Cigarette smoking	• Nonsmoker
• Peripheral arterial disease	• Poor diet	• Healthy (Dietary Approaches to Stop Hypertension (DASH)-like) diet
• End-stage renal or chronic kidney disease	• Physical inactivity	• Physical activity goal for adults < 20 y of age: > 150 min/wk moderate intensity, > 75 min/wk vigorous intensity, or combination
• Diabetes	• Obesity (especially abdominal location)	• BMI < 25 kg/m^2
• 10-y Framingham global risk > 10%	• Dyslipidemia (total cholesterol > 200 mg/dL, HDL-C < 50 mg/dL, or treated for dyslipidemia)	• Total cholesterol < 200 mg/dL (untreated)
	• HTN (SBP > 120 mm Hg, DBP > 80 mm Hg, treated HTN, or history of pregnancy-induced HTN)	• BP < 120/< 80 mm Hg (untreated)
	• Family history of premature CAD (< 55 y in men, < 65 y in women)	
	• Metabolic syndrome or history of preeclampsia or gestational diabetes	
	• Poor exercise capacity on exercise treadmill test and/or abnormal heart rate recovery after stopping exercise	
	• **Family history of premature CVD occurring in first-degree relatives in men < 55 y of age or in women < 65 y of age**	
	• **Autoimmune diseases (e.g., SLE or RA)**	

CAD, coronary artery disease; BMI, body mass index; HDL-C, high-density-lipoprotein cholesterol; SBP, systolic blood pressure; DBP, diastolic blood pressure; BP, blood pressure; CVD, cardiovascular disease; HTN, hypertension. SLE, systemic lupus erythematosus; RA, rheumatoid arthritis.

Adapted from ACC/AHA guidelines 2011 update. *JACC*. 2011;57:1404–1423.

The guidelines are grouped into three main areas: lifestyle interventions, major risk factor interventions, and preventive drug interventions. Table 46.2 lists the class I and class IIa recommendations for primary or secondary prevention of CVD in women. These guidelines are suggested as a starting point, with therapy tailored to the needs of each individual patient.

TABLE 46.2 Evidence-Based Guidelines for Prevention of Heart Disease in Women

Lifestyle interventions	Major risk factor interventions	Preventive drug interventions
• **Class I recommendations**		
Smoking cessation	Maintain optimal BP (< 120/80 mm Hg) with lifestyle modification	ASA in high-risk women (known CAD, cerebrovascular disease, PAD, AAA, ESRD, CKD, diabetes, and 10-y Framingham risk > 20%)
Exercise: 150 min/wk of moderate intensity exercise (e.g., brisk walking), 75 min/wk of vigorous intensity exercise (e.g., running), or combination	Pharmacotherapy for BP ≥ 140/90 mm Hg (≥130/80 mm Hg in CKD or diabetes). Thiazide should be initial agent unless compelling indications for β-blockers and/or ACE inhibitor/ARB exist (e.g., ACS/MI)	Clopidogrel therapy for high-risk women intolerant of ASA
Weight loss to BMI < 25 kg/m^2 and waist circumference ≤ 35"	Control of lipids through lifestyle modification (LDL-C < 100 mg/dL, HDL-C > 50 mg/dL, triglycerides < 150 mg/dL, and non–HDL-C [total cholesterol–HDL-C] < 130 mg/dL)	β-Blockers for at least 1 y and up to 3 y in women after MI and ACS, with normal LV function. Use indefinitely if LV dysfunction present
Cardiovascular rehabilitation in those with recent ACS or PCI, angina, and recent CVA, PAD, or CHF	Pharmacotherapy of lipids in those with CAD or diabetes to goal LDL-C < 100 mg/dL	ACE inhibitors in those after MI or with clinical CHF, LV dysfunction (LVEF ≤ 40%), or diabetes. If intolerant of ACE inhibitor, ARB can be substituted
Diet counseling to promote intake of fruits and vegetables, whole grain and high-fiber foods, and fish at least two times per week. Limit consumption of saturated fat, cholesterol, alcohol, sodium, and *trans*-fatty acids	Pharmacotherapy of lipids in those with LDL-C ≥ 130 mg/dL after lifestyle modification and presence of multiple risk factors (or if LDL-C ≥ 160 mg/dL in those with multiple risk factors, even if Framingham risk < 10%)	Aldosterone blockade after MI in symptomatic women with LVEF ≤ 40% who are without renal dysfunction or hyperkalemia and who are already on an ACE inhibitor and β-blocker
	Pharmacotherapy of lipids in those with LDL-C ≥ 190 mg/dL regardless of other risk factors	

TABLE 46.2 Evidence-Based Guidelines for Prevention of Heart Disease in Women (Continued)

Lifestyle interventions	Major risk factor interventions	Preventive drug interventions
	Maintain HbA_{1C} < 7% in diabetics	
• **Class IIA recommendations**		
	Goal LDL-C < 70 mg/dL is reasonable in the very high risk (known CAD + multiple major risk factors, severe and poorly controlled risk factors, or diabetes)	Low-dose ASA therapy (81 mg daily or 100 mg on alternate days) in women ≥65 y if benefits outweigh risk of bleeding
• **Class IIB recommendations**		
ω-3 Fatty acid in the form of fish or capsule (e.g., EPA 1,800 mg/d) may be considered in women with hypercholesterolemia or hypertriglyceridemia for primary or secondary prevention	Pharmacotherapy with niacin or fibrates when HDL-C is low or non–HDL-C is elevated in high-risk women (after LDL-C goal reached)	

AAA, abdominal aortic aneurysm; ACE, angiotensin-converting enzyme; ACS, acute coronary syndrome; ARB, angiotensin II receptor blocker; ASA, aspirin; BMI, body mass index; BP, blood pressure; CAD, coronary artery disease; CHF, congestive heart failure; CKD, chronic kidney disease; CVA, cerebrovascular accident; EPA, eicosapentaenoic acid; ESRD, end-stage renal disease; HbA_{1C}, glycosylated hemoglobin; HDL-C, high-density-lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol; LV, left ventricular; LVEF, left ventricular ejection fraction; MI, myocardial infarction; mm Hg, millimeters of mercury; PAD, peripheral arterial disease; PCI, percutaneous coronary intervention.

Adapted from ACC/AHA guidelines 2011 update. *JACC.* 2011;57:1404–1423.

In general, it is suggested that the initial evaluation begin with a complete history, specifically eliciting symptoms of CVD, as well as a complete physical examination, with particular attention to blood pressure, BMI, and waist size. Laboratory evaluation should follow, including fasting lipids and glucose levels. During the evaluation, assessment of Framingham risk should be performed, as well as depression screening in those women with known CVD. **All class I lifestyle interventions** should be employed in **all women**, regardless of risk level.

If the woman is at **high risk** (established CAD, cerebrovascular disease, peripheral arterial disease, abdominal aortic aneurysm, diabetes, chronic kidney disease, or Framingham risk > 20%), the **class I major risk factor and preventive drug interventions** should be initiated (see Table 46.2). Consideration should also be given to some of the class II recommendations, particularly the **LDL-C goal of < 70 mg/dL**.

There are some interventions that should not be considered under any circumstances. Table 46.3 lists those therapies that are **contraindicated** based on the results of recent clinical trials.

Novel risk factors, such as CRP (used as inclusion criteria in JUPITER), and newer screening modalities may have a role in the future, but this role is not yet defined. Further research is needed in these areas before they can be incorporated into the guidelines.

TABLE 46.3 Class III Interventions (Ineffective, Possibly Harmful in Cardiovascular Disease Prevention in Women)

Hormone replacement therapy or selective estrogen receptor modulators
Antioxidant vitamin supplementation (vitamin E, vitamin C, and β-carotene)
Folic acid with or without vitamin B_6 or B_{12} (Folic acid supplementation should be used in the childbearing years to prevent neural tube defects)
ASA in healthy women < 65 y

ASA, aspirin.

Adapted from ACC/AHA guidelines 2011 update. *JACC.* 2011;57:1404–1423.

VIII. CURRENT PROGRESS AND FUTURE INNOVATIONS. Despite clinical trial data that document the benefits of multiple therapeutic interventions, women are still inadequately treated. In fact, despite the vast amount of data on statins, the 1999 to 2000 National Health and Nutrition Examination Survey (NHANES) reported that only 10.2% of women with hyperlipidemia were receiving therapy compared with 14% of men. Men, when treated, were also much more likely to reach their goal LDL-C. Strikingly, in a study of patients receiving care in an academic medical practice, women with diabetes were the group most likely to be inadequately treated for their modifiable CVD risk factors. Furthermore, even higher risk patients (women with ACS) have been shown to be less aggressively treated than their male counterparts.

Despite the aggressive campaigns by the AHA and other organizations, women are still not well informed regarding their personal risk for heart disease. In the 2003 AHA-sponsored survey of women, only 40% considered themselves either "very well" or "well" informed about heart disease, even fewer in the most at-risk minorities. Although nearly all of the women were comfortable discussing their risk for CHD with their physician, only 38% reported that their physician had actually discussed this risk with them. This highlights the need for health-care providers to bridge this knowledge gap and seize the opportunities to discuss risks and risk factor modification with patients. Subsequently, health-care providers should aggressively treat the appropriate women based on guideline recommendations in order to improve long-term outcomes.

The population is aging, and the incidence of CVD is only likely to increase, unless we begin to institute preventive therapies earlier, and to aggressively continue them over a woman's lifespan. More attention should be paid by health-care providers to promote a woman's awareness of her risk for CVD as well as instituting therapies aggressively aimed at prevention that are tailored to a woman's specific needs.

Further research is needed in the area of gender-specific differences in CAD and all of its manifestations, as well as many of the pharmacologic and interventional therapies used in its treatment. Research that delves further into novel risk factors and the additional value that can be provided over traditional risk factors in terms of assessing risk for CVD, especially in women, is needed as well. Ongoing genetics research, as well as research related to sex hormones, could also provide useful information for tailoring gender-specific therapy. Novel imaging strategies such as cardiac Positron Emission Tomography (PET) with assessment of myocardial blood flow (MBF), are being studied and may provide important information. This may be especially important in women, given the difficulty with noninvasive diagnosis of obstructive CAD. Hopefully, once some of these diagnostic and therapeutic modalities become available, there will be appreciable changes in the occurrence and outcomes of CVD in women.

Exercise Electrocardiographic Testing

I. INTRODUCTION

A. Exercise electrocardiographic testing is a field in flux. In the past decade, it has become clear that ST-segment changes during exercise have low sensitivity and specificity in the evaluation of coronary artery disease (CAD) and are poor predictors of risk. This may be partially due to the fact that stable obstructive plaques, which typically result in exercise-mediated ischemia, are less relevant to myocardial infarction (MI) and sudden cardiac death than unstable nonobstructive plaques. Although the bulk of obstructive CAD screening has now shifted towards various stress imaging modalities, many of the physiologic parameters measured during exercise have emerged as powerful prognostic indicators. As such, the main uses of exercise electrocardiographic testing should be *evaluation of prognosis* and as *a gateway to other imaging modalities.* Stand-alone testing for CAD diagnosis is reserved for patients with *intermediate risk for CAD* and should be ordered with a careful understanding of the limitations of the test for this purpose.

1. The **advantages** of exercise electrocardiographic testing are its ability to assess a variety of prognostic markers, most importantly **functional capacity**, which is a powerful predictor of mortality, widespread availability, safety, ease of administration, and relatively low cost. The assessment of functional capacity may be particularly advantageous in patients with valvular heart disease and congenital heart disease whereupon recognition of functional limitation is often difficult to ascertain by history alone.
2. **Disadvantages.** As a screening test for CAD in persons without symptoms, exercise electrocardiography is generally not helpful or indicated. It has a **low sensitivity and specificity,** which can be improved with careful selection of the patient population undergoing testing.

B. **Submaximal exercise electrocardiographic testing** (i.e., testing at submaximal heart rate, discussed later) is a useful assessment before hospital discharge for **patients who have had MI**. The advantages are as follows:

1. It assists in setting **safe levels** of exercise (exercise prescription) and reassuring patients and families.
2. It is beneficial in **optimization of medical therapy**, in triage for intensity of follow-up testing and care, and in recognition of exercise-induced ischemia and arrhythmias.
3. For patients with uncomplicated MI who have received reperfusion therapy, submaximal exercise testing may be safely **performed as early as 3 days after MI**, with maximal exercise testing 3 to 6 weeks later.

II. INDICATIONS.

The indications for exercise electrocardiographic testing are divided on the basis of the degree of likelihood of disease or severity of diagnosed disease, use in valvular heart disease, and use in congenital heart disease (Table 47.1).

TABLE 47.1 ACC/AHA Guidelines for Exercise Testing

Exercise testing in the diagnosis of obstructive CAD

Class I[a]

- Adult patients (including those with complete right bundle branch block or < 1 mm of resting ST depression) with an intermediate pretest probability of CAD on the basis of sex, age, and symptoms

Class IIa

- Patients with vasospastic angina

Class IIb

- Patients with a high pretest probability of CAD on the basis of age, symptoms, and sex
- Patients with a low pretest probability of CAD on the basis of age, symptoms, and sex
- Patients with < 1 mm of baseline ST depression and taking digoxin
- Patients with electrocardiographic criteria of left ventricular hypertrophy and < 1 mm of baseline ST depression

Class III

- Patients with baseline electrocardiographic abnormalities
  - Preexcitation (Wolff-Parkinson-White) syndrome
  - Electronically paced ventricular rhythm
  - > 1 mm of resting ST depression
  - Complete left bundle branch block
- Patients with a documented myocardial infarction or prior coronary angiographic findings of disease and an established diagnosis of CAD (ischemia and risk can be determined with testing)

Risk assessment and prognosis among patients with symptoms or a history of CAD

Class I

- Patients undergoing initial evaluation with suspected or known CAD (exceptions in class 2b), including those with complete right bundle branch block or < 1 mm of resting ST depression
- Patients with suspected or known CAD previously evaluated, now presenting with marked change in clinical status
- Low-risk unstable angina patients 8–12 h after presentation who have been free of active ischemic or heart failure symptoms
- Intermediate-risk unstable angina patients 2–3 d after presentation who have been free of active ischemic or heart failure symptoms

Class IIa

- Intermediate-risk unstable angina patients with initial cardiac markers that are normal, a repeat electrocardiographic study without significant change, cardiac markers 6–12 h after symptom onset that are normal, and no other evidence of ischemia during observation

Class IIb

- Patients with baseline electrocardiographic abnormalities
  - Preexcitation (Wolff-Parkinson-White) syndrome
  - Electronically paced ventricular rhythm
  - 1 mm or more of resting ST depression

(Continued)

TABLE 47.1 ACC/AHA Guidelines for Exercise Testing (*Continued*)

Complete left bundle branch block or any interventricular conduction defect with QRS duration > 120 milliseconds

Patients with a stable clinical course who undergo periodic monitoring to guide treatment

Class III

Patients with severe comorbidity likely to limit life expectancy and/or candidacy for revascularization

High-risk unstable angina patients

After acute myocardial infarction

Class I

Before discharge for prognostic assessment, activity prescription, or evaluation of medical therapy (submaximal at about 4–6 d)

Early after discharge for prognostic assessment and cardiac rehabilitation if the predischarge exercise test was not performed (symptom limited, about 14–21 d)

Late after discharge for prognostic assessment, activity prescription, evaluation of medical therapy, and cardiac rehabilitation if the early exercise test was submaximal (symptom limited, about 3–6 wk)

Class IIa

After discharge for activity counseling or exercise training as part of cardiac rehabilitation of patients who have undergone coronary revascularization

Class IIb

Patients with electrocardiographic abnormalities

Complete left bundle branch block

Preexcitation (Wolff-Parkinson-White) syndrome

Left ventricular hypertrophy

Digoxin therapy

Electronically paced ventricular rhythm

> 1 mm of resting ST depression

Periodic monitoring for patients who continue to participate in exercise training or cardiac rehabilitation

Class III

Severe comorbidity likely to limit life expectancy or candidacy for revascularization

Patients with acute myocardial infarction and uncompensated congestive heart failure, cardiac arrhythmia, or noncardiac conditions that severely limit exercise ability

Before discharge, patients who have been selected for or have undergone cardiac catheterization (stress imaging tests are recommended)

Exercise testing for persons without symptoms or known CAD

Class I

None

Class IIa

Asymptomatic persons with diabetes mellitus to start vigorous exercise

Class IIb

Persons with multiple risk factors

TABLE 47.1 ***Continued***

Men older than 45 y and women older than 55 y without symptoms
- Who plan to start vigorous exercise (especially if sedentary)
- Who are involved in occupations in which impairment might affect public safety
- Who are at high risk for CAD because of other diseases

Class III
- Routine screening of men or women without symptoms

Exercise testing for persons with valvular heart disease

Class I
- None

Class IIa
- Patients with chronic AR and equivocal symptoms to assess functional capacity and symptomatic response

Class IIb
- Asymptomatic patients with AS may be considered to elicit exercise-induced symptoms and abnormal blood pressure responses
- In asymptomatic or symptomatic patients with chronic AR (with radionuclide angiography) for assessment of left ventricular function

Class III
- Exercise testing should not be performed in symptomatic patients with AS

Exercise testing for persons with congenital heart disease

Class I
- None

Class IIa
- Asymptomatic young adults < 30 y of age to determine exercise capability, symptoms, and blood pressure response
- Adolescent or young adult patient with AS who has a Doppler mean gradient > 30 mm Hg or a peak velocity > 50 mm Hg if the patient is interested in athletic participation or if the clinical findings and Doppler findings are disparate
- Asymptomatic young adult with a mean Doppler gradient > 40 mm Hg or a peak Doppler gradient > 64 mm Hg or when the patient anticipates athletic participation or pregnancy
- As part of the initial evaluation of adolescent and young adult patients with TR and serially every 1–3 y
- In patients with atrial septal defect with symptoms that are discrepant with clinical findings or to document changes in oxygen saturation in patients with mild or moderate PAH
- In patients with subvalvular AS testing to determine exercise capability, symptoms, ECG changes or arrhythmias, or increase in LVOT gradient is reasonable in the presence of otherwise equivocal indications for intervention
- In patients with supravalvular AS (along with other imaging modalities) testing can be useful to evaluate the adequacy of myocardial perfusion

Class IIb
- In patients with aortic coarctation, testing may be performed at intervals determined in consultation with the regional ACHD center

(Continued)

TABLE 47.1 ACC/AHA Guidelines for Exercise Testing (*Continued*)

Class III

Patients with atrial septal defect or patent ductus arteriosus with severe PAH

Symptomatic patients with AS or those with repolarization abnormality on ECG or systolic dysfunction on echocardiography

[a]*Class 1*, conditions for which there is evidence or agreement that a given procedure or treatment is useful and effective; *Class 2*, conditions for which there is conflicting evidence or a divergence of opinion about the usefulness or efficacy of a procedure or treatment; *Class 2a*, weight of evidence or opinion is in favor of usefulness and efficacy; *Class 2b*, usefulness or efficacy is less well established on the basis of evidence and opinion; *Class 3*, conditions for which there is evidence or general agreement that the procedure or treatment is not useful or effective and in some cases may be harmful. CAD, coronary artery disease; AR, aortic regurgitation; AS, aortic stenosis; TR, tricuspid regurgitation; PAH, pulmonary arterial hypertension; ECG, electrocardiogram; LVOT, left ventricular outflow tract; ACHD, adult congenital heart disease.

III. CONTRAINDICATIONS. Contraindications to exercise testing are divided into absolute and relative categories (Table 47.2).

IV. LIMITATIONS OF EXERCISE ELECTROCARDIOGRAPHIC TESTING. Before ordering an exercise electrocardiography test, the physician should have an understanding of Bayes' theorem and the limitations of the test.

A. Bayes' theorem states that the probability of a positive test result is affected by the likelihood (i.e., conditional probability) of a positive test result among the population that has undergone the test (i.e., pretest probability). The higher the probability that a disease is present in a given individual before a test is ordered, the higher is the probability that a positive test result is a true-positive test result. Pretest probability is determined on the basis of symptoms, age, sex, and risk factors and can be divided into very low, low, intermediate, and high (Table 47.3).

B. Sensitivity and specificity. The likelihood that an abnormal electrocardiographic finding indicates CAD is much higher for an older person with multiple risk factors than for a young person with no risk factors. Sensitivity and specificity vary with the population being tested.

1. Exercise electrocardiographic testing is **best used** in the evaluation of a patient at intermediate risk with an atypical history or a patient at low risk with a typical history.
2. For the general population, the sensitivity is 68% and the specificity is 70%. Values are lower for persons at low risk.
3. Exercise electrocardiographic testing has a higher sensitivity and specificity for **persons at high risk**. For most of these patients, however, invasive testing is preferred for a more definitive diagnosis and possible intervention. Excluding patients with left ventricular hypertrophy or resting ST depression and those taking digoxin also improves sensitivity and specificity.

TABLE 47.2 Contraindications to Exercise Testing

Absolute contraindications
Acute myocardial infarction (within 2 d)
High-risk unstable angina
Uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise
Symptomatic, severe aortic stenosis
Uncontrolled symptomatic heart failure
Acute pulmonary embolus or pulmonary infarction
Suspected or known dissecting aneurysm
Active or suspected myocarditis, pericarditis, or endocarditis
Acute noncardiac disorder that may affect exercise performance or be aggravated by exercise (e.g., infection, renal failure, or thyrotoxicosis)
Considerable emotional distress (psychosis)
Relative contraindications
Left main coronary stenosis or its equivalent
Moderate stenotic valvular heart disease
Resting diastolic blood pressure > 110 mm Hg or resting systolic blood pressure > 200 mm Hg
Electrolyte abnormalities (e.g., hypokalemia and hypomagnesemia)
Fixed-rate pacemaker
High-degree atrioventricular block
Frequent or complex ventricular ectopy
Ventricular aneurysm
Uncontrolled metabolic disease (e.g., diabetes, thyrotoxicosis, and myxedema)
Chronic infectious disease (e.g., mononucleosis, hepatitis, and acquired immunodeficiency syndrome)
Neuromuscular, musculoskeletal, or rheumatoid disorders exacerbated by exercise
Advanced or complicated pregnancy
Hypertrophic cardiomyopathy and other forms of outflow tract obstruction
Mental impairment leading to inability to cooperate

Adapted from Kenney WL, Humphrey RH, Bryant CX, eds. *ACSM's Guidelines for Exercise Testing and Prescription.* Baltimore, MD: Williams & Wilkins, 1995; from Fletcher GF, Fletcher GF, Blair SN, et al. Statement on exercise. Benefits and recommendations for physical activity programs for all Americans. A statement for health professionals by the Committee on Exercise and Cardiac Rehabilitation of the Council on Clinical Cardiology, American Heart Association. *Circulation.* 1992;86:340–344; and from Gibbons RJ, Balady GJ, Bricker JT, et al. ACC/AHA 2002 guideline update for exercise testing: a report of the American College of Cardiology/American Heart Association Task Force on practice guideline (committee on exercise testing). *J Am Coll Cardiol.* 2002;40:1531–1540.

C. Positive predictive value (PPV). After pretest probability and the sensitivity and specificity are known, PPV can be calculated. PPV is a measure of the likelihood that an abnormal test finding represents a true-positive result. It is highly dependent on pretest probability (i.e., prevalence of disease) in the population being tested. For example, in a population at low risk, the PPV of electrocardiographic exercise testing is only 21%, but in a population at high risk, PPV rises to 83%.

TABLE 47.3 Pretest Probability of Coronary Artery Disease according to Age, Sex, and Symptoms

Age (y)	Sex	Typical/ definite angina pectoris	Atypical/ probable angina pectoris	Nonanginal chest pain	Asymptomatic
30–39	Men	Intermediate	Intermediate	Low	Very low
	Women	Intermediate	Very low	Very low	Very low
40–49	Men	High	Intermediate	Intermediate	Low
	Women	Intermediate	Low	Very low	Very low
50–59	Men	High	Intermediate	Intermediate	Low
	Women	Intermediate	Intermediate	Low	Very low
60–69	Men	High	Intermediate	Intermediate	Low
	Women	High	Intermediate	Intermediate	Low

V. PATIENT PREPARATION

A. Instructions. Table 47.4 provides a typical list of instructions given to patients before testing.

B. Medications

1. Before diagnostic testing, **cardiovascular drugs are withheld** at the discretion of and under the guidance of the supervising physician. This greatly increases the sensitivity of the test.
   a. **β-Blockers** pose a special problem. Patients taking β-blockers often do not have an adequate increase in heart rate to achieve the level of stress needed for the test. Abrupt withdrawal of β-blockers is to be discouraged because of reflex tachycardia. The best possible solution is to withdraw the β-blocker over several days before an exercise test, if the test is for diagnostic purposes. This is not always possible, however, because of time constraints or the necessity of drug therapy. In these cases, the records should reflect β-blocker use at the time of testing.
   b. **Digoxin** may cause problems in test interpretation. To avoid a reading that cannot be used to confirm a diagnosis, digoxin should be withheld for 2 weeks before testing.
2. Patients undergoing diagnostic testing should take their **other usual medications** on the day of the test to reproduce more closely the conditions outside the exercise laboratory.

VI. EXERCISE PROTOCOLS.

There are advantages and disadvantages to each exercise protocol (Table 47.5). Selection depends on the patient characteristics, the equipment available, and the familiarity and comfort of the testing personnel with the protocol.

A. An **optimal protocol** achieves peak workload and maximizes the sensitivity and specificity of the test.

1. **Workload.** An optimal protocol incorporates a **gradual increase** in the level of work, so that the patient's true peak workload can be determined. If there are large increases in workload, maximum oxygen consumption ($M\dot{V}O_2$ max) may

TABLE 47.4 Patient Preparation

Patients should refrain from ingesting food, alcohol, or caffeine or using tobacco products within 3 h of testing.
Patients should be rested for the assessment, avoiding significant exertion or exercise on the day of the assessment.
Patients should wear clothing that allows freedom of movement, including walking or running shoes, and a loose-fitting shirt with short sleeves that buttons down the front. They should not wear restrictive undergarments during the test.
Outpatients should be warned that the evaluation may be fatiguing and that they may wish to have someone available to drive them home afterward.
If the test is for diagnostic purposes, it may be helpful for patients to discontinue prescribed cardiovascular medication after discussion with their physician. Antianginal agents alter the hemodynamic response to exercise and significantly reduce the sensitivity of electrocardiographic changes for ischemia. Patients taking intermediate- or high-dose β-blockers should taper their medication over a 2–4-d period to minimize hyperadrenergic withdrawal responses.
If the test is for functional purposes, patients should continue their medication regimen on their usual schedule so that the exercise responses will be consistent with responses expected during exercise training.
Patients should bring a list of their medications with them to the assessment.

Reproduced with permission from Kenney WL, Humphrey RH, Bryant CX, eds. *ACSM's guidelines for Exercise Testing and Prescription*. Baltimore, MD: Williams & Wilkins; 1995.

fall between two levels. The test is also more comfortable for the patient if the increases in workload are not large.

2. **Duration.** The optimal duration for an exercise test is **8 to 12 minutes**. Periods longer than this measure muscular endurance rather than cardiovascular fitness. Periods shorter than this do not allow adequate time for the patient to warm up and achieve maximum workloads.
3. **Stage length.** Steady-state oxygen consumption is reached after about 2 minutes of exercise at a given workload. The optimal protocol would have stage lengths of **2 to 3 minutes**.
4. **Exercise method.** Although **bicycle riding** is a better method for testing, **treadmill testing** is more commonly used in the United States.
   a. The primary physiologic **advantage of bicycle riding** is the ability to take **direct measurements** of workload in watts, which has direct linear relation to $M\dot{V}O_2$. With a **treadmill**, the examiner can only **estimate workload** because workload depends on the efficiency of walking, the weight of the patient, and the change in energy expenditure between walking and running. Other advantages of a bicycle are the stable platform that it provides for electrocardiographic and blood pressure recordings, the smaller amount of space it occupies, quieter use, and a lower initial cost of equipment.

B. Protocol options

1. **Bruce protocol**
   a. **Advantages.** The Bruce protocol has been widely used in the past and is often the basis of older studies; therefore, **comparisons are easier**. Because the Bruce protocol has a final stage that cannot be completed, it is a good protocol for a highly fit person.
   b. **Disadvantages**
      (1) The main disadvantage of the Bruce protocol is the **large increments of change in workload between stages**. These large increases mean that

TABLE 47.5 Common Exercise Protocols

4	3.5	1	—	—	—	—	—	—	1.0	0	—	—

MET, metabolic equivalent; mph, miles per hour.

peak workload falls somewhere between stages for many people. This is a problem in evaluating functional capacity and may result in a lower sensitivity for the test.

(2) The fourth stage of the Bruce protocol is an awkward stage that can be run or walked, resulting in divergent oxygen costs and workloads.

2. **Modified Bruce protocol.** Developed for less-fit persons, the modified Bruce protocol adds additional stages 0 and 1/2. These stages, at 1.7 mph (2.7 km/h) with 0% and 5% grades, respectively, provide a **lower workload for persons with poor cardiovascular fitness**. However, even these workloads may be too heavy for some debilitated patients and may result in premature fatigue.
3. **Other protocols.** Protocols superior to the Bruce protocol have been developed. These protocols have more gradual increases in workload and can be modified to suit the individual.
   a. The **Naughton protocol** is good for older or debilitated persons and allows a gradual increase in workload.
   b. The **Balke protocol** is good for younger, fit persons. It maintains a speed of 3, 3.5, or 4 mph (4.8, 5.6, or 6.4 km/h) and increases the grade every 2 minutes.
   c. The **Cornell protocol** is good for a wider range of fitness levels depending on starting grade. It allows for a gradual increase in grade and speed and may be started at 0%, 5%, or 10% grade, depending on fitness level.
   d. **Ramp protocols** are computer-driven protocols that continuously increase workload until maximum exertion is reached. This is the ultimate in continuous advancement, but steady state may not be reached at any given workload.

VII. DATA

A. Electrocardiographic data. Although not the only data that should be examined, electrocardiographic changes garner the most attention in test interpretation. The **portion of the electrocardiogram (ECG) most sensitive to ischemia** is the ST segment. The pathophysiologic mechanism of the ST change is net depression caused by a current of ischemia from the affected myocardial cells. The TP segment may be useful at rest and should be used when possible; however, it shortens or disappears with exercise. Baseline electrocardiographic abnormalities that can obscure the correct diagnosis of ST changes are listed in Table 47.6.

1. **ST-segment changes**
   a. **Measurement of the ST segment.** There is no clear consensus as to where to measure the ST segment. Traditionally, it is measured 80 milliseconds past the J point, but some investigators suggest measuring at the J point or at the midpoint of the ST segment (using the end of the T wave or the peak of the T wave to determine the end of the segment) (Fig. 47.1A).

A

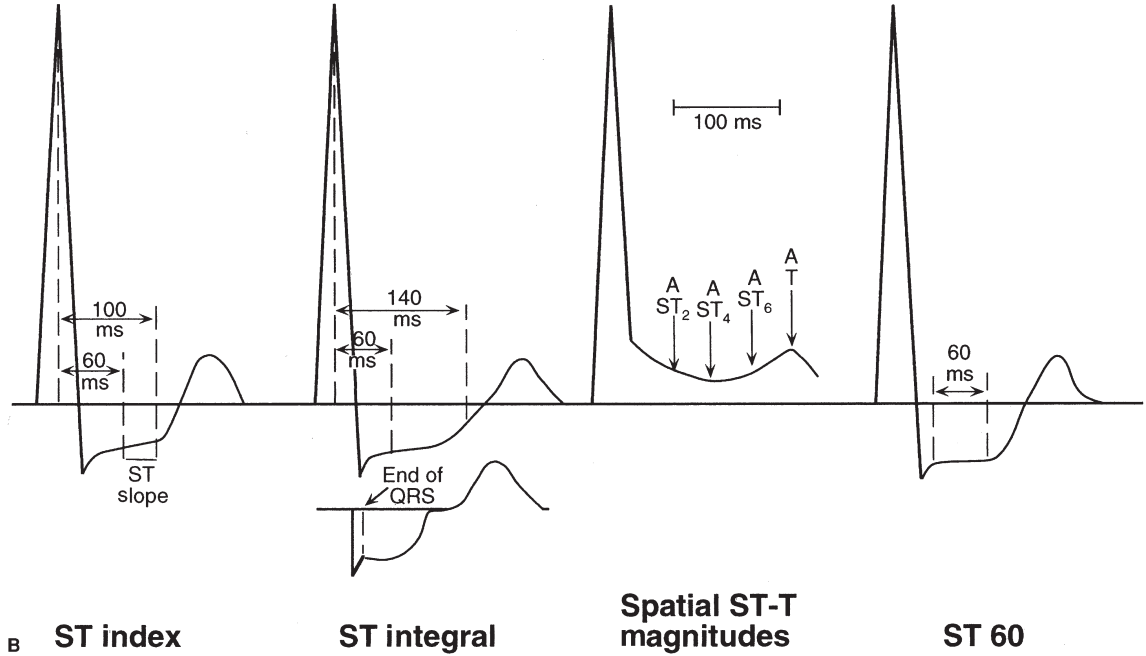

FIGURE 47.1 **(A)** Blomqvist recommended using the end of the T wave for measuring the midpoint of the ST segment, but Simons used the peak of the T wave. This change was made to have a more stable end point, because the end of the T wave is much more difficult to find than the peak of the T wave. **(B)** The ST integral, as defined by Sheffield, required that the end of the QRS complex, or J junction, be found and that the area measurement stop as soon as the ST segment crossed the isoelectric line or as the T wave began. The ST integral used by most commercial systems initiates the area at a fixed period after the R wave and then ends 80 milliseconds thereafter.

b. **ST-segment changes** are measured from the isoelectric baseline, which can be determined from the PR interval. If the ST segment is elevated at rest, any depression that occurs with exercise is still measured from the isoelectric line; early repolarization of the ST segment at rest is normal. If, however, the ST segment is depressed at rest, any further depression should be measured from the baseline ST segment (Fig. 47.1B).

c. **Normal response.** During exercise, there is depression of the J junction that is maximal at peak exercise and returns to baseline during recovery. This normal depression is upsloping and typically < 1 mm below the isoelectric line 80 milliseconds after the J point.

d. **ST depression** does not localize the area of ischemia.

(1) ST depression of at least 1 mm that is horizontal or downsloping is abnormal, as is upsloping ST depression of at least 2.0 mm.

(2) Baseline ST abnormalities are less likely to represent exercise-induced myocardial ischemia, and the baseline ST depression should be subtracted from the peak ST depression.

(3) **Criteria that increase the probability of ischemia** are the **number of leads** involved (i.e., more leads increase the probability of ischemia), the **workload** at which the ST depression occurs (i.e., lower workload increases probability), the **angle of the slope** (i.e., a downsloping angle has a higher probability than a horizontal one), **ST-segment adjustment relative to heart rate (ST/HR index)**, the **amount of time in recovery** before normalization of the ST segment (i.e., longer recovery increases the probability), and possibly the **magnitude of the depression**. Changes in the lateral leads, particularly V_5, are more specific than in any of the other leads. Changes in the inferior leads alone are likely to be a false-positive result.

e. The **meaning of ST elevation** depends on the presence or absence of Q waves of prior MI.

(1) ST-segment elevation **with Q waves of prior MI** is a common finding among patients who have had MI. It occurs among up to 50% of patients with anterior MI and 15% of patients with previous inferior MI, and it is not caused by ischemia. The mechanism is thought to be dyskinetic myocardium or ventricular aneurysms. There may even be reciprocal ST-segment depression. Patients with more extensive Q waves have more pronounced ST elevation. These patients typically have a lower ejection fraction than those without elevated ST segment with a Q wave. These changes do not imply ischemia (although they may imply viability) and should be interpreted as normal.

(2) ST-segment elevation **without Q waves of prior MI** represents marked transmural myocardial ischemia. ST elevation may also indicate the location of the ischemia. This finding should be interpreted as abnormal.

f. **ST normalization,** or the lack of ST changes during exercise, **may be a sign of ischemia.** This phenomenon occurs when ischemic ST depression and ST elevation cancel one another. This effect is rare, but it should be considered in tests of patients with no electrocardiographic changes but with a high likelihood of CAD.

2. **R waves may change in amplitude** during exercise. There is no diagnostic value in these changes.

3. **T-wave and U-wave changes**

a. The **T wave** normally decreases gradually in early exercise and begins to increase in amplitude at maximal exercise. One minute into recovery, the T wave should be back to baseline. T-wave **inversion is not a specific marker of ischemia** and may occur normally.

TABLE 47.7 Absolute and Relative Indications for Termination of an Exercise Test

Absolute indications
Acute myocardial infarction or suspicion of myocardial infarction
Onset of moderate to severe angina or increasing anginal pain
Drop in systolic blood pressure with increasing workload accompanied by signs or symptoms or drop below resting pressure
Serious arrhythmias (e.g., second- or third-degree atrioventricular block, sustained ventricular tachycardia or increasing premature ventricular contractions, and atrial fibrillation with fast ventricular response)
Signs of poor perfusion, including pallor, cyanosis, or cold and clammy skin
Unusual or severe shortness of breath
Central nervous system symptoms, including ataxia, vertigo, visual or gait problems, or confusion
Technical inability to monitor the electrocardiogram
Patient's request
Relative indications
Pronounced electrocardiographic changes from baseline > 2 mm of horizontal or downsloping ST-segment depression or > 2 mm of ST-segment elevation except in aVR
Any chest pain that is increasing
Physical or oral manifestations of severe fatigue or shortness of breath
Wheezing
Leg cramps or intermittent claudication (grade 3 on 4-point scale)
Hypertensive response (systolic blood pressure > 260 mm Hg and diastolic blood pressure > 115 mm Hg)
Less serious arrhythmias such as supraventricular tachycardia
Exercise-induced bundle branch block that cannot be differentiated from ventricular tachycardia
General appearance

Adapted from Kenney WL, Humphrey RH, Bryant CX, eds. *ACSM's Guidelines for Exercise Testing and Prescription. 5th ed.* Baltimore, Md: Williams & Wilkins; 1995 and from Fletcher GF, Blair SN, et al. statement on exercise. Benefits and recommendations for physical activity programs for all Americans. A statement for health professionals by the Committee on Exercise and Cardiac Rehabilitation of the Council on Clinical Cardiology, American Heart Association. Circulation. 1992;86:340–344

   b. If the U wave is upright at baseline, **U-wave inversion** may be associated with ischemia, left ventricular hypertrophy, and valvular disease.

4. **Arrhythmias.** Table 47.7 lists abnormal arrhythmias that may occur during exercise. Ectopic atrial and ventricular beats during exercise are not predictive of outcome, but ventricular ectopy during recovery may be associated with worse outcome. Sustained ventricular tachycardia and ventricular fibrillation are abnormal but occur rarely.
5. **Time to resolution of changes.** The longer into recovery that it takes for electrocardiographic changes to resolve, the higher is the probability that they are important. Rapid recovery (< 1 min) indicates less likelihood of disease and that disease if present is less severe.

6. Bundle branch block or conduction delay. Exercise-induced left bundle branch block is predictive of a worse outcome.

B. Age-predicted maximum heart rate (APMHR). Many formulas have been developed to predict maximum heart rate (MHR). These formulas are generated by measuring the MHR in a sample population and plotting a regression line against various factors that may affect heart rate. There is a great deal of scatter on either side of the regression line, and the fit of the line seldom reaches an r value > 0.9. Because MHR decreases with age, most equations incorporate age into the estimation. The two most common formulas are as follows:

$$\text{APMHR} = 220 - \text{age}$$

$$\text{APMHR} = 200 - \tfrac{1}{2}\,\text{age}$$

The APMHR may be much lower or much higher than a person's actual measured MHR. **Heart rate should not be used as an indicator of maximal exertion or in the decision to terminate testing, except in a submaximal test**. If MHR does not exceed 85% of APMHR during testing and there are no substantial electrocardiographic changes, the test is usually read as nondiagnostic. If there are substantial electrocardiographic changes, the test is read as abnormal, regardless of the heart rate achieved.

C. Rating of perceived exertion (RPE) is a better marker of maximal level of exertion.

1. A useful indicator of percentage of maximum workload achieved is the **RPE scale**. This is a subjective scale used to rate how much effort the subject feels he or she is expending during an exercise test. The subject should be advised to rate how he or she feels overall and not according to an individual element such as leg fatigue. Although subjective, the scale has been shown to be reproducible, and maximum ratings correspond well with maximum exertion.
   a. The **Borg scale** is used most often. The original scale ranges from 6 to 20, which is meant to correspond to a heart rate increase from 60 to 200 beats/min during exercise.
   b. The **modified Borg scale** ranges from 0 to 10. The scale includes word anchors, which are important for an accurate assessment of work level. The scales are not linear, and at higher workloads, the changes in RPE are closer together.
2. A maximal level of exertion is marked by a score > 18 (Borg scale) or 9 (modified Borg scale), respiratory quotient > 1.1 (if carbon dioxide exchange is monitored), and overall patient appearance.

D. In addition to electrocardiographic monitoring, **blood pressure monitoring** is an important aspect of the exercise test for safety and for the diagnosis of CAD. It should be checked in each walking stage. It may not be practical to check blood pressure while the subject is running.

1. **Systolic blood pressure** (SBP) normally rises during exercise. A **failure of SBP to rise** with increasing workload or a drop in SBP usually indicates the presence of CAD and is an indication to **terminate testing**.
2. **Diastolic blood pressure** decreases with exercise and may be audible down to 0 during vigorous activity. Unlike SBP, diastolic blood pressure is not useful in diagnosis or safety monitoring.

E. Symptoms. The presence or absence of symptoms and their change over time are included in the final report.

F. Functional capacity. Functional testing is a powerful marker for prognosis. Persons who achieve > 6 metabolic equivalents (METs) of workload have a significantly lower mortality rate than those who do not achieve this workload, regardless of electrocardiographic changes. On the basis of age and workload achieved, functional capacity can be divided into five classifications (Table 47.8). Among 3,400 patients with no history of diagnosed CAD undergoing exercise testing at the Cleveland Clinic, those with average or better classifications had a 2.5-year mortality of < 2% compared with 6%

TABLE 47.8 Functional Capacity Classifications by Age and Sex

Age (y)	Low[a]	Fair	Average	Good	High
Women					
20–29	< 7.5	8–10.3	10.3–12.5	12.5–16	> 16
30–39	< 7	7–9	9–11	11–15	> 15
40–49	< 6	6–8	8–10	10–14	> 14
50–59	< 5	5–7	7–9	9–13	> 13
60–69	< 4.5	4.5–6	6–8	8–11.5	> 11.5
Men					
20–29	< 8	8–11	11–14	14–17	> 17
30–39	< 7.5	7.5–10	10–12.5	12.5–16	> 16
40–49	< 7	7–8.5	8.5–11.5	11.5–15	> 15
50–59	< 6	6–8	8–11	11–14	> 14
60–69	< 5.5	5.5–7	7–9.5	9.5–13	> 13

[a]Functional capacities are given in metabolic equivalents.

and 14% for those who were in the fair and poor groups, respectively. The adjusted relative risk for fair or poor functional capacity in this population was almost 4.

VIII. TERMINATION OF EXERCISE TESTING. The American Heart Association (AHA) and American College of Sports Medicine (ACSM) have developed very similar indications for exercise termination (Table 47.7). The decision when to terminate a test ultimately relies on the expertise and judgment of those performing the test.

A. Absolute indications are all serious findings. A drop in SBP with increasing workload is a particularly ominous sign and usually, but not always, indicates the presence of severe CAD.

B. Relative indications for termination of testing are findings that should increase the level of concern and vigilance among those administering the test and possibly cause cessation of testing. Relative indications for termination rely heavily on the judgment of the personnel performing the test, and the decision to continue the test should not be made lightly (Table 47.7).

C. Indications for termination of submaximal exercise testing include any one of the following end points:

(1) Signs or symptoms of ischemia
(2) Achievement of a workload of 6 METs
(3) Eighty-five percent of the APMHR
(4) Heart rate of 110 beats/min for a patient taking β-blockers
(5) A score on the Borg RPE of 17 or modified Borg RPE of 7

D. Postexercise recovery

1. In **all routine exercise tests, a cool-down period** adds safety to the test. The length of the cool-down period may vary from 30 seconds to several minutes, depending on the person. A general rule is to allow enough time for the heart rate to drop to < 110 beats/min. A shorter cool-down period increases the sensitivity of exercise ECG because of increased venous return; resuming the supine position leads to increased wall stress. This same mechanism also increases the risk of testing.

2. The exception to observing a cool-down period may be made for exercise echocardiography, in which it is important to image the subject when he or she is as close as possible to MHR.

IX. INTERPRETATION OF DATA. An experienced clinician must interpret an exercise electrocardiographic test. Although the terms *positive* and *negative* are often used, these terms do not accurately describe the results of an exercise electrocardiographic test and should be avoided. The information to include in an exercise electrocardiographic report is listed in Table 47.9.

A. Exercise electrocardiographic test results can be normal, abnormal, normal except for, or nondiagnostic (Table 47.10). Nondiagnostic tests are those in which the subject does not achieve 85% of APMHR and has no abnormal electrocardiographic changes or in which baseline electrocardiographic changes are present that obscure ST changes (Table 47.6).

B. Prognosis

1. The **Duke nomogram** (Fig. 47.2) is a simple chart that factors in ST-segment deviation, amount of angina during exercise, and exercise capacity to give an estimate of a 5-year survival and average annual mortality. This nomogram was derived by means of regression analysis and can be a useful tool in determining prognosis and the degree of aggressiveness needed in treating a patient. The **Duke treadmill score (DTS)** is a numeric form of the nomogram and has been validated in several studies as an important predictor of mortality:

$$\text{DTS} = \text{duration of exercise (in minutes)} - (5 \times \text{maximal ST-segment deviation}) - (4 \times \text{angina score})$$

TABLE 47.9 Elements of Conclusion Section of a Modern Exercise Test Report

Exercise protocol used, duration of exercise, peak treadmill speed and grade, maximum heart rate and percentage of age-predicted maximum heart rate achieved, resting and peak blood pressure, and symptoms
Negative/positive/equivocal standard ST-segment response to exercise
"The ST/HR index of ≤ 1.6 μV/beats/min is consistent with the absence of obstructive coronary disease and makes anatomically, functionally, and prognostically important coronary disease unlikely"; "The ST/HR index > 1.6 μV/beats/min is consistent with the presence of obstructive coronary disease and predicts increased cardiovascular risk
The estimated functional capacity of (*x* METs) predicts (high/low) risk of all-cause mortality
The Duke treadmill score of (*x*) predicts a cardiac mortality of (*x*%) per year over the next 5 y. This implies a (low/intermediate/high) risk
The chronotropic response index of (0.*xx*) predicts an (increased/decreased) risk of death compared with the Duke treadmill score. For patients not on β-blockers, a value ≤ 0.80 raises concerns; for patients on β-blockers, a value ≤ 0.62 is abnormal
The heart rate recovery of (*x* beats/min) further predicts an (increased/decreased) risk of death
The presence/absence of frequent ventricular ectopy during recovery further increases/decreases predicted risk of death

TABLE 47.10 Guidelines for Interpretation of Results of Exercise Electrocardiography

Variable	Normal	Normal except for	Abnormal
Symptoms	Neuromuscular chest pain	Angina as an isolated finding	Syncope
	Fatigue, shortness of breath, and leg or joint pain	Atypical angina	Angina when associated with ST- or T-wave changes, including borderline
		Chest discomfort of questionable causation	Angina when associated with exercise hypotension
		Claudication	
		Dizziness and lightheadedness	
		Other noteworthy symptoms	
Blood pressure response (mm Hg)	SBP increases > 10 but is < 230 at peak	SBP ≥ 230 at peak exercise	Any drop in SBP as exercise intensity increases
	DBP increases ≤ 10 but is < 120 at peak	DBP ≥ 120 at peak exercise	
	DBP stays the same or decreases	DBP increases ≥ 12 from rest if peak is ≥ 100	
	DBP increases ≥ 12 from rest but peak is < 100		
Arrhythmias	Occasional PVCs	Paroxysmal SVT	Sustained SVTs, AF, atrial flutter, or junctional rhythm
	PACs	Increased frequency of PVCs or couplets during exercise	Nonsustained VT
	Frequent PACs or PVCs at rest that abate during exercise	Isolated run of nonsustained VT	Second- or third-degree AV block

(Continued)

TABLE 47.10 Guidelines for Interpretation of Results of Exercise Electrocardiography (*Continued*)

Variable	Normal	Normal except for	Abnormal
	Chronic AF, atrial flutter	Ventricular couplets	AV dissociation
		Paroxysmal escape rhythms	Exercise induced before excitation
			Idioventricular rhythm
			Very abnormal
			Sustained VT (≥30 s)
			VF/cardiac arrest
			Asystole
ST segments	< 1.0 mm ST depression or elevation	Borderline ST changes (0.5–0.9 mm ST depression)	≥1.0 mm H or D ST depression
		ST elevation in leads in area of prior MI	≥1.5 mm U ST depression
		T-wave inversion	≥1.0 mm U ST depression if associated with anginal symptoms
		Pseudonormalization of resting T-wave abnormalities	≥1.0 mm ST elevation in leads without Q waves or not over a prior MI
			Very abnormal
			≥2.0 mm H or D ST depression
			≥2.5 mm U ST depression
			≥2.0 mm ST elevation in leads without Q waves or not over a prior MI
Functional capacity	Normal or mildly impaired exercise tolerance	Low exercise tolerance	Inability to achieve 3 MET workload

AF, atrial fibrillation; AV, atrioventricular; D, downsloping; DBP, diastolic blood pressure; H, horizontal; MET, metabolic equivalent; MI, myocardial infarction; PAC, premature atrial contraction; PVC, premature ventricular contraction; SBP, systolic blood pressure; SVT, supraventricular tachycardia; U, upsloping; VF, ventricular fibrillation; VT, ventricular tachycardia.

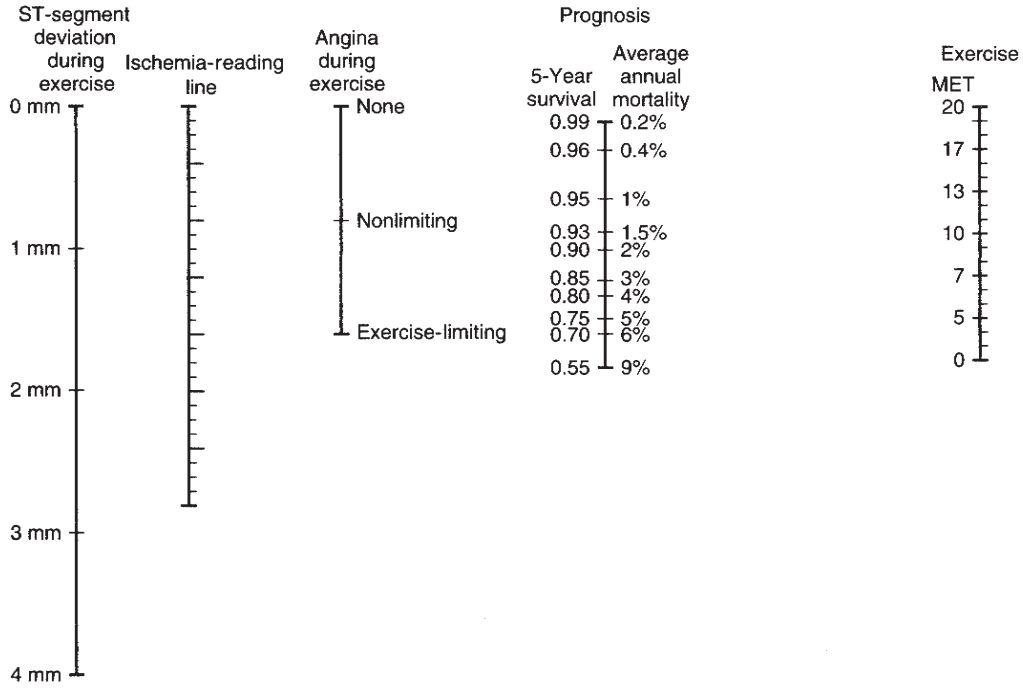

FIGURE 47.2 Duke nomogram for estimation of the prognosis. MET, metabolic equivalent.

In the previous equation, 0 = no angina, 1 = non–test-limiting angina, and 2 = exercise-limiting angina.

Low risk: DTS ≥ +5
Intermediate risk: DTS −10 to < +5
High risk: DTS < −10

2. The **heart rate recovery**, defined as the difference in heart rate at peak exercise and at 1 minute after cessation of exercise, has important prognostic significance. A heart rate recovery of 12 beats/min or less is considered abnormal during an upright cool-down period. For patients assuming an immediate supine position, such as during exercise echocardiography, a value of < 18 beats/min is considered abnormal.
3. The **chronotropic response index (CRI)** is a measure of MHR in relation to chronotropic reserve. A normal response is defined as a CRI of > 0.8 (0.62 for patients on β-blockers):

$$\text{CRI} = \frac{\text{peak HR} - \text{resting HR}}{\text{APMHR} - \text{resting HR}}$$

4. **Ventricular ectopy in recovery** from exercise, including frequent ventricular ectopics (> 7/min), couplets, bigeminy, trigeminy, ventricular tachycardia, and ventricular fibrillation, has been shown to be predictive of all-cause mortality. These findings in recovery are a better predictor of death than ventricular ectopy during exercise.
5. A published nomogram (1) for patients with suspected CAD and a normal ECG undergoing exercise treadmill testing demonstrates how a simple combination of clinical and stress-testing variables can be used to predict mortality.

X. POTENTIAL COMPLICATIONS. Complications of exercise electrocardiographic testing are rare, but they do occur (Table 47.11). Exercise testing of healthy persons without CAD rarely results in cardiac complications, which are most likely to occur among persons with underlying CAD. Several researchers have looked at large numbers of unselected persons involved in various activities to determine risk.

A. Cardiac arrest

1. For the **general population**, there is approximately 1 cardiac arrest per 565,000 person-hours of exercise.
2. Among **persons with known CAD**, there is an estimated 1 arrest per 59,000 person-hours of vigorous activity. Exercise testing may precipitate acute coronary symptoms. Acute MI has been reported in approximately 1.4 per 10,000 exercise tests.
3. Among **persons at low risk** for CAD, however, the risk for cardiac arrest during exercise testing is much lower. In one study, no complications occurred in 380,000 exercise tests of young persons with presumably no heart disease.

B. Arrhythmic complications are a potential hazard of exercise testing (Table 47.10). Arrhythmias are more likely among persons with a history of arrhythmia. In this population, they occur in 9% of tests compared with an overall incidence of 0.1%.

1. **Atrial fibrillation** is the most common arrhythmia that occurs during testing, occurring in 9.5 per 10,000 tests.
2. **Ventricular tachycardia** is less common, occurring in 5.8 per 10,000 tests.
3. **Ventricular fibrillation** is even less common, occurring 0.67 times per 10,000 tests.

C. Deaths during exercise testing are exceedingly rare among well-monitored patients, but may occur in 1 of 25,000 tests. If death occurs, it is usually caused by sudden cardiac death or MI.

TABLE 47.11 Potential Medical Complications of Exercise Electrocardiographic Testings

Cardiovascular complications

Cardiac arrest
Ischemia
- Angina
- Myocardial infarction

Arrhythmias
- Supraventricular tachycardia
- Atrial fibrillation
- Ventricular tachycardia
- Ventricular fibrillation

Bradyarrhythmias
- Bundle branch blocks
- Atrioventricular nodal blocks

Congestive heart failure
Hypertension
Hypotension
Aneurysm rupture

Underlying medical conditions predisposing to increased complications

Hypertrophic cardiomyopathy
Coronary artery anomalies
Idiopathic left ventricular hypertrophy
Marfan's syndrome
Aortic stenosis
Right ventricular dysplasia
Congenital heart defects
Myocarditis
Pericarditis
Amyloidosis
Sarcoidosis
Long QT syndrome
Sickle cell trait
Sudden death

Pulmonary complications

Exercise-induced asthma
Bronchospasm
Pneumothorax

CHAPTER 48

Santosh S. Oommen

Nuclear Cardiac Imaging

I. INTRODUCTION. Nuclear cardiology has an integral role in the noninvasive detection of coronary artery disease (CAD), assessment of myocardial viability, and stratification of risk. It imparts improved sensitivity and specificity over standard exercise stress testing. For example, the average sensitivity and specificity of single-photon emission computed tomography (SPECT) with technetium 99m have been reported to be 90% and 74%, respectively—though the exact performance characteristics depend on the prevalence of the disease in the population being studied. Nuclear imaging can provide functional and prognostic information that is quantifiable, reproducible, and readily obtainable in diverse patient populations.

II. INDICATIONS (Table 48.1)

A. Diagnosis of CAD. Nuclear perfusion studies are performed to establish noninvasively the diagnosis of CAD in the following situations: history of **stable angina; chest pain of unclear causation; unstable angina** after stabilization; **abnormal exercise test result** without symptoms; **risk stratification** in the setting of multiple factors thought to confer a high likelihood of subclinical CAD; scheduled standard exercise testing in the setting of an **abnormal electrocardiogram** (ECG; due to left ventricular hypertrophy with associated repolarization changes, ST depression >1 mm, manifest pre-excitation pattern on ECG, digoxin use, left bundle branch block, or ventricular-paced rhythm); and previously **nondiagnostic graded exercise test**.

B. Assessment of the physiologic importance of known CAD. Perfusion imaging can assist in the determination of the functional significance of a coronary stenosis that is in the "moderate-to-severe" (50% to 70%) range on angiographic evaluation. It can therefore be useful to evaluate a specific coronary lesion before proceeding to percutaneous intervention. This remains an accepted indication for nuclear perfusion imaging, although its use for this purpose is being supplanted by other modalities that can assess the functional significance of coronary lesions at the time of angiography (e.g., fractional flow reserve).

C. Assessment after therapeutic intervention. In the past, perfusion imaging was often performed as a routine follow-up procedure after percutaneous intervention and coronary artery bypass grafting (CABG). More recent recommendations on appropriate use of this modality suggest that routine screening in *asymptomatic* patients who have been successfully revascularized by either method is not necessarily warranted, except in the evaluation of patients more than 5 years after CABG. On the other hand, radionuclide perfusion imaging is certainly appropriate in patients who have undergone prior revascularization and are presenting with recurrent symptoms consistent with coronary ischemia.

D. Risk stratification. With nuclear imaging, it is possible to stratify risk among patients with stable angina or unstable angina, those who have had myocardial infarction (MI), and those about to undergo noncardiac operations.

TABLE 48.1 Appropriate Indications for Myocardial Perfusion Imaging—Based on the ACCF/ASNC/ACR/AHA/ASE/SCCT/SCMR/SNM 2009 Appropriate Use Criteria for Cardiac Radionuclide Imaging

Patient group	Condition	Imaging technique
ER patient with chest pain	For risk stratification in pt with *possible* ACS. Initial serum markers and enzymes. ECG is nondiagnostic.	Rest perfusion imaging (with ECG gating, if possible).
	For CAD diagnosis in pt with *possible* ACS and nondiagnostic ECG. Negative serum markers and enzymes or normal rest perfusion scan.	Same-day rest/stress (ECG-gated) myocardial perfusion imaging.
Acute MI/unstable angina	Assessment of LV function.	Rest myocardial perfusion imaging with ECG gating (rest gated radionuclide angiography is alternative option).
ST-elevation MI	Measurement of infarct size and residual viable myocardium, in an unrevascularized asymptomatic stable patient after completion of the infarct.	Rest myocardial perfusion imaging with ECG gating or with stress perfusion imaging with ECG gating.
	Thrombolysis without coronary angiogram, to identify inducible ischemia and myocardium at risk.	Rest and stress myocardial perfusion imaging, with ECG gating whenever possible.
Non–ST-elevation MI/unstable angina	In an unrevascularized stable asymptomatic patient after completion of the infarct, to determine the extent and severity of inducible ischemia, either in the distribution of the "culprit" vessel or in remote myocardium.	Rest and stress myocardial perfusion imaging, with ECG gating whenever possible.
	In individuals whose angina is stabilized on medical therapy or in whom the diagnosis is uncertain, to identify the extent and severity of inducible ischemia.	Rest and stress myocardial perfusion imaging, with ECG gating whenever possible.
	To assess the functional significance of a coronary stenosis on angiography.	Rest and stress myocardial perfusion imaging.

TABLE 48.1 Appropriate Indications for Myocardial Perfusion Imaging—Based on the ACCF/ASNC/ACR/AHA/ASE/SCCT/SCMR/SNM 2009 Appropriate Use Criteria for Cardiac Radionuclide Imaging (*Continued*)

Patient group	Condition	Imaging technique
CAD diagnosis in an individual with an intermediate probability of disease and/or risk stratification in someone with an intermediate or high likelihood of disease *and* able to exercise to 85% MPHR or more	Those with pre-excitation, LVH, on digoxin, or >1 mm ST-segment depression on resting ECG.	Rest and exercise stress myocardial perfusion imaging, with ECG gating whenever possible.
	Individuals with left bundle branch block or ventricular-paced rhythm.	Rest and vasodilator stress myocardial perfusion imaging, with ECG gating whenever possible.
	Patients with an intermediate- or high-risk Duke treadmill score.	Rest and exercise stress myocardial perfusion imaging, with ECG gating whenever possible.
	In an individual with prior abnormal myocardial perfusion scan and new or worsening symptoms.	Repeat rest and exercise stress myocardial perfusion imaging, with ECG gating whenever possible.
CAD diagnosis in an individual with an intermediate probability of disease and/or risk stratification in someone with an intermediate or high likelihood of disease *and* not able to exercise	To identify the extent, severity, and location of inducible ischemia.	Rest and vasodilator stress myocardial perfusion imaging, with ECG gating whenever possible.
Detection of CAD in patients with ventricular tachycardia	Patients without known CAD or ischemic equivalent.	Rest and stress myocardial perfusion imaging, preferably exercise stress, with ECG gating whenever possible.
Detection of CAD in patients with syncope.	Patients with intermediate and high risk for CHD and no ischemic equivalent.	Rest and stress myocardial perfusion imaging, preferably exercise stress, with ECG gating whenever possible.

(*Continued*)

TABLE 48.1 Appropriate Indications for Myocardial Perfusion Imaging—Based on the ACCF/ASNC/ACR/AHA/ASE/SCCT/SCMR/SNM 2009 Appropriate Use Criteria for Cardiac Radionuclide Imaging (*Continued*)

Patient group	Condition	Imaging technique
Prior to intermediate- and high-risk noncardiac surgery	Initial diagnosis of CAD in those with at least one clinical risk factor for adverse perioperative CV events, and poor (<4 METSs) or unknown functional capacity.	In those able to exercise, rest and exercise stress myocardial perfusion imaging, with ECG gating whenever possible *or* In those unable to exercise, rest and vasodilator stress myocardial perfusion imaging, with ECG gating whenever possible.
	In individuals with established or suspected CAD and poor (<4 METS) or unknown functional capacity.	In those able to exercise, rest and exercise stress myocardial perfusion imaging, with ECG gating whenever possible *or* In those unable to exercise, rest and vasodilator stress myocardial perfusion imaging, with ECG gating whenever possible.
	Diagnosis of CAD in patients with left bundle branch block or ventricular-paced rhythm and at least one risk factor for adverse perioperative CV events.	Rest and vasodilator stress myocardial perfusion imaging, with ECG gating whenever possible.
	In suspected or established CAD, prognostic assessment of those with left bundle branch block or ventricular-paced rhythm on rest ECG.	Rest and vasodilator stress myocardial perfusion imaging, with ECG gating whenever possible.
Equivocal SPECT myocardial perfusion scan	Clinically indicated SPECT perfusion study is equivocal for CAD diagnosis or risk stratification purposes.	Rest and adenosine or dipyridamole stress PET myocardial perfusion study.

(*Continued*)

TABLE 48.1 Appropriate Indications for Myocardial Perfusion Imaging—Based on the ACCF/ASNC/ACR/AHA/ASE/SCCT/SCMR/SNM 2009 Appropriate Use Criteria for Cardiac Radionuclide Imaging (*Continued*)

Patient group	Condition	Imaging technique
CAD patient with systolic dysfunction and CHF, with little or no angina	Prediction of improvement in regional/global LV function following revascularization.	Stress/redistribution/reinjection thallium 201 SPECT perfusion imaging *or* Rest/redistribution SPECT perfusion imaging *or* Myocardial perfusion plus FDG PET metabolic imaging *or* Resting sestamibi SPECT perfusion imaging.
	Prediction of improvement in natural history following revascularization.	Stress/redistribution/reinjection thallium 201 SPECT perfusion imaging *or* Rest/redistribution thallium 201 SPECT perfusion imaging *or* Myocardial perfusion plus FDG PET metabolic imaging.

ACS, acute coronary syndrome; CAD, coronary artery disease; CHF, congestive heart failure; CV, cardiovascular; ECG, electrocardiogram; ER, emergency room; FDG, [18F]fluoro-2-deoxyglucose; LV, left ventricular; LVH, left ventricular hypertrophy; MI, myocardial infarction; MPHR, maximal age-predicted heart rate; PET, positron emission tomography; pt, patient; SPECT, single-photon emission computed tomography.

E. Identification of prior MI among patients with angiographically normal coronary arteries is afforded by nuclear imaging.

F. Assessment of left ventricular (LV) function. Although nuclear imaging is used less often for this purpose than in the past—due to the desire to reduce patients' radiation exposure when possible—gated blood pool imaging remains an accurate method of determining the ejection fraction.

III. CONTRAINDICATIONS.

In addition to standard contraindications to exercise stress testing, specific considerations apply uniquely to nuclear imaging in general and the subgroup of dipyridamole stress perfusion studies.

A. General contraindications to nuclear studies. Nuclear imaging is contraindicated for patients who have had **iodine 131 therapy** within 12 weeks; **technetium 99m studies** within 48 hours, including bone, lung, multigated acquisition (MUGA), liver, tagged red blood cell (to evaluate gastrointestinal bleeding), and renal scans; **indium 111 scans** within 30 days; **gallium 67 scans** within 30 days; and **oral intake** within 4 hours (except for water).

B. Contraindications to dipyridamole, adenosine, or regadenoson administration include allergy to any of these agents, allergy to aminophylline, ongoing theophylline therapy (must be discontinued for 36 hours), history of uncontrolled asthma or reactive airway disease, significant atrioventricular nodal block, and caffeine consumption within 12 to 24 hours.

IV. EQUIPMENT.

The most basic tool in nuclear imaging is the **gamma or scintillation camera**, which is used to detect gamma rays (i.e., x-ray photons) produced by the chosen radionuclide. Three types of gamma camera exist.

A. A single-crystal camera consists of one large sodium iodide crystal. Other essential elements of this camera include the **collimator**, a lead device that screens out background or scattered photons, and the **photomultiplier**, an electronic processor that translates photon interactions with the crystal into electric energy.

1. Electric signals from the photomultiplier are processed by the **pulse height analyzer** before reaching a final form. Only signals in a specified energy range are incorporated into the interpreted images. The range recognized by the pulse height analyzer is adjustable and is established on the basis of the radiopharmaceutical used.
2. **Digitalization** of the single-crystal camera has greatly enhanced its performance.

B. A **multicrystal camera** works with an array of crystals with increased count detection capability. Because of the availability of an individual crystal to detect scintillation at any given time, this type of camera can be used to detect many more counts than can a single-crystal camera.

C. In the case of positron emission tomography (PET) scanning, a **positron camera** is a gamma camera used to detect the photon products of positron annihilation. Interaction between a positron and an electron causes annihilation, with the generation of two high-energy photons (511 keV) that travel in opposite directions.

1. An array of multiple concentric rings of crystals constitute a positron camera. Each crystal is linked optically to multiple photomultipliers. The crystals are oriented in diametric pairs in such a way that each pair of crystals must be struck simultaneously by annihilation photons to record activity. Background interference and stray photon energy are automatically accounted for, and artifact is limited.
2. Most positron cameras contain **bismuth germanate** for annihilation photon detection. The clinical utility and radiopharmaceuticals for PET are discussed in Section **X**.

V. MECHANICS AND TECHNIQUES

A. Image acquisition. Basic perfusion imaging can be performed by means of **planar** and **tomographic** techniques. The tomographic, or SPECT, method is the most commonly used today.

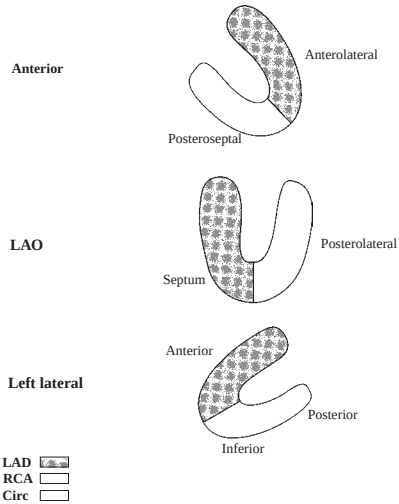

FIGURE 48.1 Standard planar views and vascular territories. Circ: circumflex artery; LAO, left anterior oblique; LAD: left anterior descending artery; RCA: right coronary artery.

1. **Planar images** are acquired in three views: **anterior, left anterior oblique (LAO)**, and **steep LAO** or **left lateral (LLAT) orientation** (Fig. 48.1). The patient is supine for anterior and LAO views but is placed in the lateral decubitus position for LLAT image acquisition. Although it allows examination of specific myocardial segments, planar imaging superimposes vascular distributions and therefore can compromise the ability to implicate a specific vascular supply when a defect is present. For example, normally perfused myocardial segments may overlap perfusion defects in a separate distribution.
2. Using **SPECT**, a series of planar images are usually obtained over a 180° arc to reconstruct a three-dimensional representation of the heart. The arc typically extends from the 45° right anterior oblique plane to the 45° left posterior oblique plane, with the patient in the supine position.
   a. Three orientations are analyzed in the final representation: **short axis, vertical long axis**, and **horizontal long axis**. A computer-generated display, the **polar map**, is also analyzed as a quantifiable representation of count density.
   b. Unlike planar imaging, **SPECT** can be used to **separate vascular territories** and improve image interpretation. SPECT, however, also **increases the time needed** for image acquisition and requires close attention to quality control issues.

B. Radiopharmaceuticals available for nuclear imaging include thallium 201, technetium 99m, and several positron imaging agents. Each possesses specific energy characteristics, kinetic profiles, and biodistribution (see below as well as Table 48.2 and Section **X** for further details).

1. **Thallium 201**
   a. **General characteristics.** Thallium 201 (i.e., thallous chloride) is a metallic element in group IIIA of the periodic table; it is produced in a cyclotron. Thallium emits gamma rays at an energy range of 69 to 83 keV and has a **half-life of 73 hours**. The biologic activity of this element is very similar to that of potassium; the ionic radii of the two elements are virtually identical. Thallium is actively transported into cells by the sodium–potassium adenosine triphosphatase (Na-K ATPase) pump.

TABLE 48.2 Characteristics of Common Perfusion Agents

Attribute	Thallium 201	Technetium 99m sestamibi	Technetium 99m tetrofosmin	Technetium 99m teboroxime
Energy (keV)	69–83	140	140	140
Dose (mCi)	2.5–3.5	20–30	20–30	20–30
Half-life (h)	74	6	6	6
Cyclotron required	Yes	No	No	No
Perfusion imaging	Yes	Yes	Yes	Yes
Viability evaluation	Yes	Yes	Yes?	No
Redistribution	Yes	Yes (minimal)	Yes (minimal)	Yes
Gating (electrocardiogram)	No	Yes	Yes	No

b. Kinetics. Approximately 5% of the administered dose of thallium 201 is distributed to the myocardium, proportionate to the blood flow delivered to the coronary circulation. Almost 85% of the thallium 201 is extracted by myocytes in the first pass.

(1) The **initial uptake** of thallium 201 by myocardium is directly related to regional blood flow. The myocardial extraction of thallium 201, however, increases at low flow rates (<10% of basal) and decreases at high flow rates (more than twice the basal rate).

(2) Washout. After initial uptake into myocytes, a state of continuous exchange across the cell membrane occurs. The distribution of this radiotracer changes after administration, and thallium 201 washes out from the myocytes, a process called **redistribution**. Thallium 201 washout generally approaches 30% at 2 to 2.5 hours after injection.

(3) Ischemic myocardium. Uptake of thallium 201 in ischemic myocardium is lower than uptake in nonischemic segments. Washout time from ischemic zones is slower than that from nonischemic zones.

(4) Over time, counts become equal in the ischemic and nonischemic regions (or thallium 201 concentration may increase in ischemic regions) so that thallium 201 concentrations in these disparate areas approach one another. This disparity is taken advantage of during thallium 201 viability imaging (described below).

2. Technetium 99m–labeled agents

a. General characteristics. Technetium 99m is a radiopharmaceutical that can be produced on-site in molybdenum 99–technetium 99m generators. It possesses several ideal imaging characteristics.

(1) Technetium 99m has a **half-life of 6 hours** and emits gamma rays with a single photopeak of 140 keV.

(2) Technetium 99m–labeled **perfusion agents** include ^{99m}**Tc-sestamibi**, ^{99m}**Tc-tetrofosmin**, and ^{99m}**Tc-teboroxime**. Although ^{99m}Tc-sestamibi and ^{99m}Tc-tetrofosmin have similar properties, ^{99m}Tc-tetrofosmin may be less sensitive at detecting ischemic changes and its use for viability detection is less well validated.

b. Kinetics. After administration of ^{99m}Tc-sestamibi, approximately 40% to 60% of the agent is extracted by the myocardium. Initial uptake of the agent

is proportional to regional myocardial blood flow, and it is bound to the inner mitochondrial membrane. ^{99m}Tc-tetrofosmin has similar pharmacokinetics to ^{99m}Tc-sestamibi.

Myocardial washout of ^{99m}Tc-sestamibi and ^{99m}Tc-tetrofosmin is very slow, and little redistribution occurs. The absence of redistribution requires two separate injections of the agent, at **rest** and at **peak exercise** (or with pharmacologic stress). This can be performed with a same-day or 2-day protocol.

VI. IMAGING PROTOCOLS

A. Thallium 201

1. **General features.** Stress imaging with thallium 201 involves **injection at peak exercise** (or with pharmacologic stress) and **immediate imaging**, followed by **redistribution images** 3 to 4 hours after injection.
   - **a.** Because of the long half-life of thallium 201 (i.e., 73 hours), to reduce the total radiation exposure to the patient, limited amounts are administered. Although a single injection is typically used because of the redistribution phenomenon, a second injection may be given to enhance the filling of reversible defects.
   - **b.** The low energy range of thallium 201 is marginal for imaging with the gamma camera because of scatter and diminished spatial resolution.
2. **Variations from standard protocol.** Exact imaging techniques vary among institutions. Initial thallium 201 doses range from 2 to 3.5 mCi, acquisition times vary from 20 to 40 seconds per image, and the number of images varies from 32 to 64 depending on whether 180° or 360° image acquisition is used.
   - **a.** The use of **360° versus 180° imaging** has been the subject of debate. With 180° tomography, contrast is better, there is less artifact, and imaging times are shorter. Slight variations also exist depending on the use of exercise stress testing or pharmacologic stress protocols.
   - **b.** When **exercise thallium 201 scintigraphy** is performed, the radionuclide (2 to 3.5 mCi) is usually injected approximately 1 minute before peak exercise to allow time for distribution. Initial images are obtained within 5 to 10 minutes of injection. Redistribution images are obtained 2.5 to 4 hours after the initial images.
   - **c.** In some cases, persistent defects that would ordinarily be interpreted as myocardial scar represent viable myocardium.
     - **(1)** For this reason, some advocate **delayed (late redistribution) imaging** 18 to 24 hours after injection. Some studies indicate that up to 40% of persistent defects exhibit radiotracer uptake after revascularization. Delayed imaging has resulted in further redistribution in as many as 45% of patients.
     - **(2)** Alternative approaches in **differentiating viable tissue from scar** include **rest reinjection** of thallium 201, in effect to boost fill-in of perfusion defects. As many as 50% of persistent defects have been shown to exhibit improved thallium 201 uptake after rest injection of 1 mCi of thallium 201, suggesting viability.
   - **d.** Minor changes in imaging protocol may be observed with **pharmacologic stress testing** with adenosine, regadenoson, dipyridamole, or dobutamine.

B. Technetium 99m.

The relative lack of redistribution requires **two injections** of technetium 99m to obtain rest and stress images.

1. **Basic protocols**
   - **a. Same-day protocol.** At peak exercise, 25 to 30 mCi of technetium 99m is injected. Rest images are obtained first, and stress imaging follows to minimize residual scintigraphic activity caused by the higher dose stress injection.

(1) **Rest images** are obtained with injection of 7 to 10 mCi of technetium 99m and image acquisition up to 1 to 1.5 hours later. Imaging is delayed because of slower liver clearance with rest injection.

(2) **Stress images** are obtained approximately 45 to 60 minutes after injection. Hepatic uptake of technetium 99m occurs within 15 to 30 minutes of injection, and the tracer is excreted into the gastrointestinal tract through the biliary system. Appearance of the tracer in the gastrointestinal tract can interfere with imaging of the inferior wall of the left ventricle.

b. The **separate-day protocol** allows time for decay of activity. Larger doses of technetium 99m can be administered for rest and stress images, and there is minimal interference between the images.

(1) Between 22 and 30 mCi of technetium 99m is injected for stress and rest imaging, separated by 1 to 2 days.

(2) The higher doses possible with the 2-day protocol produce increased count density and better image quality at the cost of inconvenience.

2. Factors that affect image quality. Consumption of a **fatty meal** can enhance biliary excretion of technetium 99m and improve image quality. Because of possible interference from noncardiac uptake, image processing with technetium 99m relies on normalization to the brightest cardiac pixel.

C. Dual isotope imaging. Use of both thallium 201 and technetium 99m substantially reduces the time required to obtain stress and rest images.

1. The patient receives thallium 201 at rest (3.5 mCi) and, immediately after rest imaging, undergoes stress. At peak stress, the patient is given an injection of 25 mCi of technetium 99m. Stress images are obtained 15 minutes later.

2. This technique makes use of the dissimilar energy levels of the two radionuclides to shorten the protocol while still allowing acquisition of ECG-gated images (because of the use of technetium 99m).

3. The sensitivity (91%) and specificity (75%) of this combination protocol are comparable to the values for conventional technetium 99m SPECT.

VII. STRESS PROTOCOLS

A. Exercise stress testing. Standard exercise testing (see Chapter 49) is frequently complemented with nuclear imaging. The radioisotope is injected at peak exercise, and time is allowed for circulation of the agents (usually at least 1 minute before termination of exercise).

B. For patients who are unable to exercise, **pharmacologic testing** is used in concert with nuclear imaging. Adenosine, regadenoson, and dipyridamole are vasodilators that are useful in noninvasive testing because of differences in coronary flow reserve. In the presence of marked coronary stenosis, the distal vessel is maximally dilated and therefore possesses little flow reserve.

1. Adenosine acts at several different receptors (A_1, A_{2A}, A_{2B}, and A_3) and thus has several physiologic effects. Its desired effect for the purpose of pharmacologic stress is to substantially enhance coronary flow in normal beds (i.e., normal flow reserve), although much less so in distributions supplied by a stenotic artery. The resultant disproportionate flow is the basis for heterogeneous radiotracer uptake.

a. Administration. Adenosine is infused at 140 μg/kg/min for 6 minutes. The radiotracer is injected after 3 minutes of infusion.

b. Side effects commonly experienced include chest pain, headache, nausea, and flushing. Atrioventricular block and bronchoconstriction are the result of effects on the A_1 and A_3 receptors, respectively.

2. Dipyridamole is an adenosine reuptake inhibitor, leading to increased extracellular concentrations of adenosine, and thus has very similar effects. It has a longer distribution half-life than adenosine, however, of approximately 25 minutes.

a. **Administration.** Dipyridamole is infused over a 4-minute period (0.142 mg/kg/min). The maximum vasodilatory effect is achieved 4 minutes after completion of the infusion, and the radiotracer is injected at this point. A slight increase in heart rate (10 beats/min) and decrease in blood pressure (10 mm Hg) are frequently observed.

b. **Side effects.** Headache, nausea, chest pain, hypotension, dizziness, and flushing have been reported. Severe side effects may necessitate reversal of the dipyridamole effect with aminophylline, given as a 50- to 100-mg intravenous bolus.

3. **Regadenoson** is a selective A_{2A} receptor agonist that has been FDA approved for clinical use in myocardial perfusion imaging since 2008. Two randomized double-blind multicenter trials—ADVANCE-MPI 1 and 2—have demonstrated the safety of this agent in a total of 1,871 patients, as well as an efficacy similar to adenosine for the detection of reversible perfusion defects on SPECT imaging.
   a. **Administration.** Regadenoson is given as a single 0.4 mg (in 5 mL) intravenous bolus and does not require adjustment for body mass index or renal or hepatic function. Its coronary hyperemic effects have an onset within 30 seconds and usually last for 2 to 5 minutes.
   b. **Side effects** of chest pain, headache, nausea, and flushing do occur with regadenoson. However, atrioventricular block and bronchoconstriction are far less common than with adenosine or dipyridamole, due to the lack of agonism of the A_1 and A_3 receptors with this A_{2A}-selective agent. Aminophylline can be given intravenously to reverse intolerable or dangerous side effects if they occur.
4. **Dobutamine** is an agonist of the β_1 and β_2 receptors and thus increases both heart rate and contractility (with a mild reduction in systemic vascular resistance).
   a. **Administration.** Infusion is begun at 5 μg/kg/min and increased every 3 minutes to a maximum dose of 40 μg/kg/min. The radiotracer is injected at maximum dose (or at 85% of age-predicted maximum heart rate), and the infusion is continued for 2 to 3 minutes.
   b. **Side effects** associated with dobutamine include ectopy, headache, flushing, dyspnea, paresthesias, and hypotension.

VIII. IMAGE INTERPRETATION

A. Standard view of normal anatomy. The uptake of radiotracer is homogeneous in persons with normal myocardial perfusion. The tracer is predominantly distributed to the left ventricle; the right ventricle usually appears as a faint, thin structure. Understanding and interpreting these images, however, requires an understanding of standard planar and SPECT views of LV anatomic features.

1. **Planar images** are represented as LAO, anterior–posterior (AP), and LLAT views.
2. Standard **SPECT views** include the short axis, vertical long axis, and horizontal long axis. The short-axis view is further divided into apical, midventricular, and basal views.
   a. As with planar views, SPECT images in various projections **correspond with specific myocardial segments** (Fig. 48.2).
   b. In addition to the standard SPECT sections, short-axis sections can be compiled into a so-called **bull's eye display** (i.e., **polar map**). This computer-generated polar map (i.e., "bull's eye" image) arranges short-axis tomographic images such that the central portion represents apical slices and the periphery consists of the basal segments.

B. Reviewing sequence. Review of nuclear images follows an organized sequence.

1. **Examine unprocessed images** for artifact, extracardiac uptake, and evidence of increased lung uptake.
2. **Compare rest and stress images** for enlargement of the LV cavity.

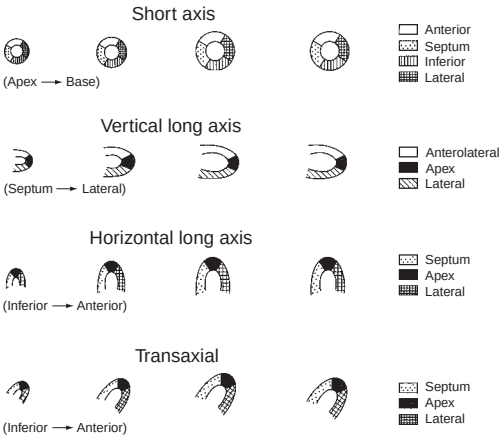

FIGURE 48.2 Standard tomographic projections and myocardial segments.

3. **Examine rest images.** Document fixed defects and the number of segments involved.
4. **Examine stress images.** Document defects and segments.
5. **Evaluate the polar map** in comparison with pooled normal images (derived from a database of patients with low probability of having CAD).
6. **Incorporate the gated SPECT images** to establish overall ventricular function and evaluate wall function in areas of questionable artifact. Segmental defects that demonstrate normal motion on gated SPECT images likely represent artifact.

C. **Characterization of defects.** Given that initial perfusion images represent regional myocardial blood flow, defects in these images represent an area of myocardium with relatively less uptake and diminished regional blood flow. Defects can be characterized as **fixed, reversible, or partially reversible** or as displaying **reverse redistribution**. (The term *redistribution* is not appropriately used in context with technetium 99m imaging.)

1. **Fixed defects.** Nonreversible or fixed defects are areas of absent tracer uptake that appear unchanged on both rest and stress images. Fixed defects can **represent scar or viable myocardium**. With thallium 201 imaging, nonreversibility suggests similar rates of clearance from the two regions.
   a. **Differentiating scar from viable myocardium** in the setting of a nonreversible defect can be accomplished through the use of **metabolic radiopharmaceuticals and PET, delayed imaging, or rest reinjection** with thallium 201. The level of tracer activity reflects viability. Severe deficits (<50% of normal counts) are less predictive of viability than are milder count deficits.
   b. Differentiating viable myocardium from scar is paramount because there is clinical and experimental evidence of improved LV function after revascularization of such hibernating regions (See Chapter 50). As methods of revascularization become increasingly applicable in an arena of increasingly complex patient problems, fully defining the so-called fixed defect through metabolic imaging assumes greater importance (see Sections **VIII.D.2** and **X.D**).
2. **Reversible defects** are present on initial stress images but resolve on rest or delayed images. This pattern is consistent with the presence of **ischemic myocardium** in the region of reversibility.

   a. In the setting of **thallium 201 imaging**, resolution of the defect is a function of variable tracer concentrations in ischemic and nonischemic segments, which approach one another as redistribution occurs, along with continuous exchange of myocyte and blood pool thallium 201. **Fill-in** of reversible defects on thallium 201 images can be enhanced by means of delayed imaging or rest reinjection.
   b. **Technetium 99m imaging**, which lacks redistribution, demonstrates reversibility on the basis of differential uptake during stress compared with rest.
3. **Partially reversible defects** are present on stress images and partially resolve on rest images but do not fill in completely. This type of defect is thought to reflect a **mixture of scar and ischemic myocardium**. Nonetheless, reversibility may be incomplete even in the absence of nonviable tissue and represent purely ischemic myocardium.
4. A pattern of **reverse redistribution** occurs when a defect appears larger on rest images or is absent on stress images but is present on rest images.
   a. Such a pattern is seen in the presence of **acute MI** when the infarct artery has been rendered patent through thrombolysis, percutaneous coronary intervention, autolysis, or another form of revascularization.
   b. The pattern is thought to reflect post-MI hyperemia with excess radiotracer uptake in a region of reperfused myocardium followed by accelerated myocardial washout of radiotracer in the defect region.
   c. The regions in question may demonstrate viability on PET imaging and do not indicate ischemia.
5. **Artifacts.** Apparent perfusion defects can be attributed to soft tissue attenuation, a problem that occurs more often with thallium 201 imaging than when a higher-energy agent (technetium 99m) is used.
   a. Common causes of the presence of artifacts include **breast attenuation** (affecting the anterolateral, septal, anteroseptal, and posterolateral walls of the ventricle) and **diaphragmatic attenuation** (predominantly altering the inferior and posterior walls).
   b. Planar images with perfusion defects seen in only a single view are suspect, and the presence of artifact must be considered.
   c. SPECT artifacts may be more elusive because of processing and reconstruction of tomographic images. However, with good technique, most are avoidable. When there is a suspicion for attenuation artifacts as above, **attenuation correction** processing techniques can be employed to account for these variables.
6. **High-risk perfusion scan.** Specific patterns of perfusion imaging that suggest high-risk coronary anatomic features include perfusion **defects in more than one vascular distribution, increased lung thallium uptake, and transient LV dilatation**.

D. Quantitative analysis. The principles of image analysis rely on visual inspection, which is fraught with observer variability.

1. **Computer-aided analysis** of planar data involves comparison of regional radionuclide activity on stress and rest images; count discordance coincides with reversibility. **SPECT** data are quantitatively analyzed by means of comparing count densities on short-axis images (displayed as a polar map) with normal count profiles. Although they improve sensitivity, these methods are **used in concert with visual analysis**.
2. **PET imaging**, although evaluated in large part in a visual manner, also possesses great clinical utility with the application of **quantitative analysis of myocardial perfusion and coronary flow reserve**. Moreover, significant advances have been made in the ability to quantify *absolute*—and not just relative—blood flow in different coronary vascular territories using PET imaging. On the basis of analysis of baseline blood flow and flow during vasodilator stress, this technique is

useful in revealing functionally important coronary lesions even in the presence of multivessel coronary disease.

The administration of adenosine, dipyridamole, or regadenoson should induce at least a twofold to threefold increase in coronary blood flow over baseline in a normal coronary vascular bed—but this "flow reserve" is not present in the setting of functionally significant epicardial coronary artery stenosis existing proximally to this bed (as discussed earlier in the chapter). Thus, relative differences in myocardial perfusion during hyperemia—which may not be appreciated on visual inspection—may be more precisely demonstrated with quantitative analysis of flow reserve. Furthermore, the ability to quantitate absolute myocardial blood flow regionally and globally may help surmount the difficulty in noninvasively diagnosing CAD in the setting of "balanced ischemia" from severe left-main or triple-vessel CAD.

IX. CLINICAL APPLICATIONS

A. Perfusion analysis

1. Detection of CAD

a. Sensitivity and specificity. Since the introduction of thallium 201 imaging in 1975, the utility of perfusion agents in the diagnosis of CAD has been well established. Quantitative planar imaging and SPECT demonstrate 90% or greater sensitivity.

(1) **Sensitivity** is affected by the number of vessels involved. Single-vessel disease is most likely to produce a false-negative finding. Multivessel CAD rarely produces a normal perfusion scan result. The **specificity** of planar imaging is 83% and that of SPECT is ~70%.

(2) In general, radionuclide imaging is best used to evaluate a population at intermediate risk for CAD. The choice of radionuclide agent seemingly has little effect on the accuracy of these techniques.

(3) The introduction of **PET**, however, has brought with it **advanced diagnostic accuracy**, with approximately 10% to 15% improvement over SPECT. The ability to detect CAD in a noninvasive manner offers numerous additional applications in risk stratification, prognosis, and imaging of acute infarction.

b. Causes of **false-positive** perfusion study results include attenuation defect, technical inadequacies, coronary vasospasm, anomalous coronary circulation, cardiomyopathy, conduction defects such as left bundle branch block, and recanalization of a thrombosed coronary artery.

c. Causes of **false-negative** perfusion study results include a submaximal exercise stress test, anti-ischemic medical therapy, collateral or overlap circulation, inaccurate interpretation of perfusion images or angiograms, acquisition of suboptimal images, presence of balanced coronary stenoses, and delay in stress imaging.

2. Risk stratification. In addition to indicators of higher risk taken from perfusion images, such as increased lung uptake, determinants in the assessment of risk are as follows.

a. Presence of reversible as opposed to fixed defects is associated with greater likelihood of cardiac events related to acute coronary syndrome at follow-up evaluation. This relation has clinical utility in a number of settings, including risk stratification after MI or in the preoperative setting. In one study involving patients who had had MI without complications, patients with single, fixed defects on thallium 201 images had a 6% cardiac event rate, compared with a rate of 51% for those with thallium 201 scans that indicated high risk of such an event.

b. Radionuclide **imaging abnormalities** have been identified as **independent predictors of subsequent infarction or death**. In general, the number of

abnormal segments identified on nuclear images can be seen as inversely proportional to survival rate. Normal findings on a nuclear perfusion study, however, suggest an excellent prognosis, with a yearly mortality rate <1% (in patients with a normal ejection fraction). The application of such prognostic information to the care of patients preparing for noncardiac operations reflects significantly on the patient's surgical risk and has an established role in preoperative evaluation and clearance. For this population, evidence of ischemia on perfusion images portends a higher risk of a perioperative cardiac event.

3. Myocardial perfusion imaging may aid in the diagnosis and risk stratification of patients with **acute coronary syndromes**.
   a. Patients with **chest pain of ill-defined origin** can be given an injection at rest of thallium 201 or technetium 99m. In the presence of true ischemia (i.e., without infarction), **reversible defects** are documented, and insight into **regional distribution of ischemia** and extent of myocardium involved is gained. The **absence of any perfusion defect with ongoing chest pain makes a diagnosis of angina less likely**.
   b. In the setting of **thrombolysis**, imaging with technetium 99m can provide important information about reperfusion or lack thereof. Injection of technetium 99m before initiation of thrombolysis captures a picture of hypoperfusion, which can, because of the extensive half-life, be imaged at a later time. Subsequent injections reveal the status of perfusion as the period after thrombolysis proceeds (i.e., persistent, large defect that represents failed reperfusion). Such applications in the setting of thrombolysis and in acute coronary syndromes have limited clinical utility because of the logistics of staffing and availability of radiopharmaceuticals.
   c. A further application that affects the arena of revascularization and management of ischemic syndromes involves **assessment of myocardial viability**.

B. Assessment of ventricular function. In addition to its use in perfusion analysis, radionuclide imaging can establish cardiac performance. Radionuclide-based assessment of ventricular function includes first-pass radionuclide angiocardiography and gated blood pool imaging.

1. **First-pass radionuclide angiocardiography** involves injection of a radionuclide and analysis as the agent passes through the central circulation.
   a. Technetium 99m–labeled agents are typically administered in bolus form, and scintigraphic data are recorded for 15 to 30 seconds after injection. Multicrystal cameras oriented in a straight anterior projection are used for detection of high count rates.
   b. This method of ventricular function analysis is more useful in evaluating **right ventricular function** than is gated blood imaging. In patients with **severe LV dysfunction**, the radiotracer may be dispersed, and proximal venous access and rapid administration may be necessary.
2. **Gated blood pool imaging**, also known as radionuclide angiography or MUGA, relies on ECG gating to correlate multiple individual images of the cardiac blood pool to specific phases of the cardiac cycle.
   a. The blood pool is labeled by means of removing a 2- to 3-mL sample of the patient's blood after the intravenous administration of stannous chloride. The sample is labeled with technetium 99m and reinjected into the patient intravenously. The stannous ions reduce the technetium, so they will not leak out of the tagged cells.
   b. A single-crystal gamma camera is used in the LAO, AP, LLAT, and sometimes left posterior oblique projections to obtain serial static images of the cardiac blood pool gated to the R-R interval.
   c. Because multiple cardiac cycles are averaged to obtain the final images, this technique is not optimal for evaluating regional wall motion. For many years, though, MUGA was considered a "gold standard" technique

for assessment of overall LV ejection fraction. Radionuclide angiography remains a well-validated and highly reproducible method of assessment of overall LV ejection fraction (and, importantly, retains this quality especially well at low ejection fractions). The use of this technique is diminishing in the current era of echocardiography and cardiac MRI.

3. **ECG-gated perfusion imaging.** Perfusion imaging with technetium 99m–labeled tracers produces sufficient count densities on individual images to allow ECG gating. The standard injection of 20 to 30 mCi of technetium 99m allows evaluation of **perfusion and function in a single study**. The *greatest* utility of ECG-gated perfusion imaging may be in elucidating perceived artifacts on perfusion images. For example, if a region has a perceived fixed perfusion defect, yet wall motion is normal in the same region, artifact becomes a more likely consideration as the cause of the filling defect.

   Comparison of this method with two-dimensional echocardiography in the evaluation of regional wall motion has shown good correlation between the two. This correlation is not applicable to stress echocardiography, however, because of the time lag from the period of stress to the acquisition of nuclear images.

X. POSITRON EMISSION TOMOGRAPHY.

PET has bolstered the evaluation of CAD by nuclear imaging techniques, both by improving blood flow imaging and by allowing evaluation of metabolic activity. Positron imaging agents can be divided into blood flow tracers and metabolic radiopharmaceuticals.

A. Blood flow tracers. A number of radiopharmaceuticals exist for the assessment of myocardial blood flow. They can be produced by a cyclotron or generator.

1. **Rubidium 82**, the most readily used blood flow tracer, can be generated on-site without the use of a cyclotron. Much like thallium 201, rubidium 82 is a potassium analogue that is actively transported into myocytes through the Na-K pump. **Uptake into myocardium** is proportionate to regional blood flow. Approximately 65% of the radiotracer is extracted at first pass. Because of a short half-life (76 seconds), rubidium 82–based imaging protocols can be used to assess myocardial blood flow rapidly (within 1 hour). However, the short half-life also precludes exercise stress PET imaging with this tracer.
2. Other perfusion agents include the cyclotron-produced **nitrogen 13 ammonia** (half-life 10 minutes) and **oxygen 15 water** (half-life 123 seconds). Image quality with **oxygen 15 water** is poor and requires extensive processing to subtract the blood pool. Rb 82 and ^{13}N-ammonia are the perfusion tracers that are used in clinical practice, with Rb 82 carrying the distinct advantage of requiring only a generator instead of a cyclotron. The image quality of ^{13}N-ammonia is excellent, although the impracticality of cyclotron production in most facilities is a limiting factor for this agent. For those facilities capable of ^{13}N-ammonia generation, however, it has the "upside" of a longer half-life than rubidium 82; thus, exercise stress cardiac PET imaging could be performed if desired.

B. Metabolic radiopharmaceuticals. Metabolic imaging with PET depends on the use of radiolabeled substrates of cardiac metabolism, largely in the form of [^{18}F] fluoro-2-deoxyglucose (FDG), carbon 11 palmitate, and carbon 11 acetate.

1. **FDG** is a glucose analogue used by ischemic myocardium because of a transition to alternative fuel sources in the hypoxic state. Ischemic myocardium diminishes the oxidation of long-chain fatty acids and increases the use of glucose as a secondary fuel source. FDG is phosphorylated to FDG-6-phosphate after transport across the cell membrane. FDG imaging therefore reflects myocardial use of exogenous glucose, and FDG is a widely used metabolic radiopharmaceutical. It has a half-life of 1.83 hours, which means it can be ordered on a daily basis by institutions that do not have an on-site cyclotron—making it the most commonly used metabolic PET imaging agent.

2. [^{11}C]Palmitate is taken up by myocytes, converted to acyl CoA, and relegated to triglyceride stores or β-oxidized to produce [^{11}C]carbon dioxide. The release of this product of β-oxidation is reflective of long-chain fatty acid oxidation in myocardium.
3. [^{11}C]Acetate is metabolized to [^{11}C]carbon dioxide after entering the tricarboxylic acid cycle. Measuring the production of [^{11}C]carbon dioxide in this setting correlates with myocardial oxygen consumption.

C. Protocols. Image acquisition with PET is similar to that with SPECT in that tomographic images are obtained in short-axis, horizontal long-axis (sagittal), and vertical long-axis (coronal) views. A positron camera consists of an array of crystals arranged in a circle. Unlike in SPECT, the camera remains stationary in PET.

1. The heart is localized with the patient's arms extended above the head. An **attenuation scan** is performed that allows the density of the surrounding thorax to be subtracted to leave only cardiac count activity. This performance of attenuation correction which makes **allowance for noncardiac interference** adds a great deal to the accuracy of PET.
2. After the attenuation scan, the **positron-emitting radiopharmaceutical is injected**, and **images are obtained** 2 to 5 minutes later. As mentioned earlier in the chapter, two photons are created by the annihilation of the emitted positron colliding with the nearest electron it meets in the tissue surrounding it. These two photons travel *exactly 180° apart* while the patient is lying in the circular scanner. This is an important concept because it means there is **no need for collimation**. The detector/analyzer merely has to "accept" the signal it receives only if a simultaneous signal strikes the detector directly across from it in the scanner. This *dramatically* improves the signal-to-noise ratio that can be achieved during imaging.
3. Metabolic imaging can be undertaken after flow imaging with the administration of 5 to 10 mCi of FDG. Tomographic images are typically obtained 30 to 50 minutes after FDG injection.

D. Patterns of perfusion and metabolic imaging. Specific patterns of perfusion and metabolic imaging are identifiable. For example, **normal flow–normal FDG (match)** indicates normal perfusion and normal metabolic activity. **Reduced flow with normal or increased FDG ("flow-metabolism mismatch")** demonstrates viability (i.e., hibernating myocardium). **Reduced flow–reduced FDG** identifies scar tissue.

E. Clinical applications

1. **Diagnosis of CAD.** Flow imaging with PET is highly sensitive and highly specific for the detection of coronary stenosis, approaching 93% for both.
   a. Higher-energy photons (511 keV), higher count densities, shorter half-life, and "built-in" attenuation correction place PET substantially ahead of SPECT in the accurate detection of CAD.
   b. As mentioned before, the ability to quantitate absolute blood flow regionally and globally may help improve the diagnosis of coronary ischemia in the setting of severe multivessel disease and balanced ischemia.
2. **Assessment of myocardial viability.** (see Chapter 50). The use of **PET with metabolic radiotracers is the standard for identifying viable myocardium**. The presence of a flow-metabolism mismatch, which indicates underperfusion in the presence of metabolically active myocytes, indicates hibernating myocardium. Revascularization of these zones as identified with PET has been shown to result in improvement in wall motion. This utility of nuclear imaging has found increasing application in the selection of patients for revascularization who have ischemic cardiomyopathy and heart failure with low ejection fraction.

CHAPTER 49

Michael P. Brunner

Stress Echocardiography

I. INTRODUCTION. Stress echocardiography (SE) is an **effective method of evaluating for myocardial ischemia**, based on the detection of **stress-induced regional wall motion abnormalities** (WMAs). Stressors include exercise, pharmacologic agents, and pacing. SE is used to **screen for coronary artery disease** (CAD), and it can help **identify the coronary vessels involved**. The accuracy of SE in the detection of significant coronary artery stenosis is 80% to 90%, which is superior to that of exercise electrocardiographic testing and comparable to that of nuclear stress imaging. In patients with left ventricular (LV) dysfunction and documented CAD, SE can **differentiate viable myocardium from scarred myocardium**, which may help predict whether LV function will improve after revascularization. As a diagnostic test for CAD, **SE is safe and relatively inexpensive** and **can be rapidly performed by experienced hands**. However, interpretation of SE images remains primarily subjective and requires a considerable learning curve. SE can also be used to assess the severity of valvular disease, hypertrophic cardiomyopathy, and exercise-induced pulmonary hypertension. In addition, it provides important prognostic information after myocardial infarction (MI) and prior to noncardiac surgery.

II. PATHOPHYSIOLOGY

A. Exercise stress testing. Myocardial ischemia results from a mismatch between oxygen supply and demand. The ischemic cascade is illustrated in Figure 49.1. Echocardiography detects ischemia by identifying new or worsening WMAs earlier in the cascade than detected by the electrocardiogram (ECG) or the onset of symptoms, but usually after the onset of worsening diastolic function. Exercise can be performed with a treadmill or an upright or supine bicycle.

B. Pharmacologic stress testing. In patients who cannot exercise, pharmacologic stressors can be used. These drugs are sympathomimetic agents or vasodilators.

1. **Sympathomimetic agents.** Myocardial oxygen demand is determined by contractility (inotropy), heart rate (chronotropy), and wall stress (preload + afterload). Sympathomimetic agents produce stress by causing an **increase in myocardial oxygen demand through increased inotropy, chronotropy, and blood pressure (BP) (afterload)**. Although a number of agents have been evaluated in combination with echocardiography, **dobutamine** is most widely used. Low-dose dobutamine has positive inotropic effects mediated through cardiac α_1 and β_1 receptors. At higher doses, it has positive chronotropic effects mediated through β_2 receptors. The plasma half-life of dobutamine is 2 to 3 minutes. The normal response to dobutamine is an increase in heart rate and hyperdynamic wall motion, with only minimal effect on end-diastolic LV volume. It can be **combined with atropine** to achieve the usual target of at least 85% of age-predicted maximum heart rate (APMHR).
2. A **vasodilator stress test** is performed with **dipyridamole** or **adenosine** infusion. These agents result in perfusion abnormalities by causing blood to be preferentially shunted away from myocardial segments supplied by stenotic coronary arteries (i.e., coronary steal) and into more normal coronary vessels. This may lead to wall motion abnormality in the perfusion territory of the stenotic coronary artery that is seen on echocardiography. These agents are less commonly used for SE. Adenosine has fewer side effects than dipyridamole, owing to the former's shorter half-life. However, because of the shorter duration of action of adenosine, the echocardiographic findings tend to be less pronounced and of shorter duration, resulting in a lower sensitivity.

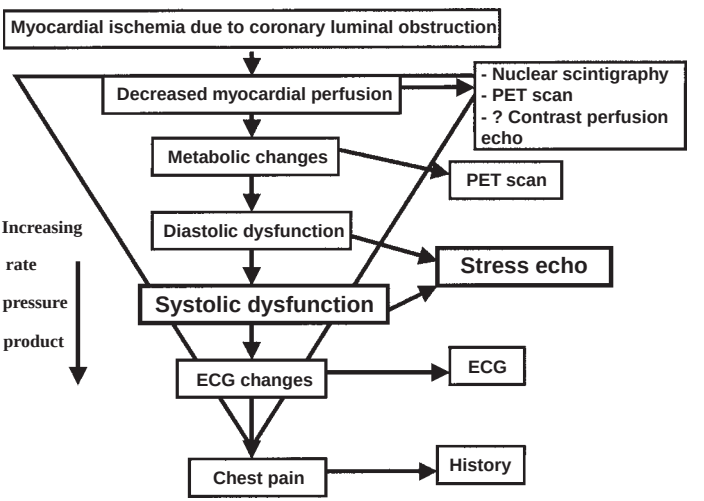

FIGURE 49.1 Ischemic cascade. PET, positron emission tomography; ECG, electrocardiogram.

3. **The 2007 American Society of Echocardiography (ASE) guidelines recommend dobutamine as the first-line agent for pharmacologic SE.** In addition, much of data for preoperative risk stratification and viability assessment using SE were derived from pharmacologic studies using dobutamine.

C. Atrial pacing. Tachycardia induced by atrial pacing is an alternative to pharmacologic testing in patients that cannot exercise. In patients with a permanent pacemaker, stress is achieved by increasing the pacing rate until the target heart rate is reached. Transvenous and transesophageal pacing are considerations in patients without a permanent pacemaker.

III. INDICATIONS AND CHOICE OF STRESSOR

A. The **indications and contraindications** for SE testing are similar to those used for exercise electrocardiographic stress testing (see Chapter 47). The addition of an imaging modality improves the sensitivity and specificity of exercise electrocardiographic stress testing. Table 49.1 lists factors that may limit the sensitivity of electrocardiographic stress testing to detect CAD; patients with these factors benefit from a stress test utilizing an imaging modality (i.e., echocardiography, nuclear scintigraphy, or positron emission tomography [PET]).

B. **Additional contraindications** to SE occur **with pharmacologic stress** and depend on the underlying pharmacologic stressor. Patients with severe bronchospastic obstructive lung disease or high-grade atrioventricular (AV) block should avoid dipyridamole and adenosine. Patients with unstable ventricular arrhythmias should avoid dobutamine infusion. **Relative contraindications to SE** include unstable angina, severe baseline hypertension, uncontrolled arrhythmias, mobile LV thrombus, critical aortic stenosis (AS), hypertrophic obstructive cardiomyopathy, and decompensated heart failure.

C. Exercise stress is preferred over nonexercise stress because it more closely reproduces daily activity and is more sensitive in the detection of ischemia, provided the patient is able to achieve an adequate level of stress. No single **exercise modality** has been shown to have superior sensitivity, although the **treadmill** is more widely accepted among patients and physicians. **Bicycle ergometry** can be performed in the upright and supine positions. Images with treadmill stress testing must be obtained after exercise, whereas images may be obtained at peak exercise with bicycle ergometry while the patient continues to exercise. The sensitivity of treadmill testing to detect ischemia is reduced if images are not rapidly obtained (< 90 seconds) after exercise. However, the treadmill usually results in a greater level of stress than is associated with bicycle ergometry, which is more dependent on patient effort.

TABLE 49.1 Factors Limiting the Sensitivity of Stress Electrocardiography to Detect Coronary Artery Disease

Left bundle branch block or other intraventricular conduction delay abnormalities
Paced rhythms
Abnormal ST segments at baseline:
Digitalis effect
Electrical left ventricular hypertrophy
Previous evidence of myocardial infarction
Nonspecific, abnormal ST-segment changes
Women (higher rate of false-positive ST-segment changes)
Left ventricular hypertrophy (even with normal-appearing electrocardiogram)

D. Up to **30% of patients referred for exercise echocardiography may not be able to achieve an adequate level of exercise stress** because of peripheral vascular disease, chronic obstructive pulmonary disease, or musculoskeletal problems. **Pharmacologic stress testing is usually indicated** in these patients.

IV. METHODOLOGY

A. Patient preparation

1. Patients should avoid heavy food intake for several hours before the test.
2. Rate-slowing agents (particularly β-blockers) blunt the normal heart rate response to exercise and may limit the ability of the patient to achieve at least 85% of the APMHR. This may reduce the sensitivity of the test results. If possible, these agents should be withheld before the stress test, unless the aim of the test is to evaluate their effectiveness in preventing exercise-induced ischemia.
3. The **standard connections for a 12-lead ECG** may be used with minor modifications to allow imaging in the parasternal and apical windows without affecting the accuracy of the exercise electrocardiographic testing results.

B. Equipment. All SE studies are conducted with **exercise electrocardiographic testing and standard hemodynamic monitoring equipment**. A SE software package on the echocardiographic machine is necessary to acquire digital images and to allow side-by-side comparison of pre-stress images with peak stress or post–peak stress images. Resuscitation equipment and a defibrillator should be readily available.

C. Performing the test

1. **Exercise SE.** Regardless of the exercise modality, a quick, complete **baseline** echocardiographic scan is obtained for all patients. Resting images are obtained in the parasternal long- and short-axis and apical two- and four-chamber views and stored digitally. An apical long-axis view may be substituted for a parasternal long-axis view if the parasternal images are suboptimal. If endocardial definition is suboptimal, intravenous ultrasound contrast should be given to optimize the images.
   a. **Treadmill exercise** is performed with standard protocols according to the functional status of the patient. Exercise is continued until at least 85% of the APMHR is reached, but it is preferably continued to the level of maximum exertion to maximize test sensitivity. APMHR equals 220 – age. **Post–peak stress images** are obtained as quickly as possible (in the left lateral decubitus position) after the patient transfers from the treadmill to the imaging table. Stress images in the same views as the baseline study are stored digitally and recorded on videotape. All post–peak stress images should be **obtained within 90 seconds of completing exercise** to maximize test sensitivity.
   b. During **upright bicycle echocardiography**, baseline images are obtained in the standard left lateral position and are repeated with the patient in the upright position on the cycle ergometer. Adequate parasternal images may be recorded by having the patient lean forward. These images are recorded and digitized to allow comparable windows for the rest and peak stress images. Cycle ergometry is started at a workload of 25 W and increased by 25 to 50 W every 2 to 3 minutes until the patient reaches his or her level of perceived maximal effort. During upright bicycle echocardiography, **images are obtained and digitized at rest, before peak, at peak, and after peak exercise**.
   c. With **supine bicycle exercise**, the entire study is performed while the patient is tilted 30° in the left lateral decubitus position, and images are obtained and digitized **at rest, before peak, at peak, and after exercise**. This exercise modality is not widely used.
   d. **Study end points** for exercise SE include **target heart rate** (85% APMHR), **severe electrocardiographic ischemia** (ST-segment depression > 5 mm), **intolerable symptoms** (chest pain and dyspnea), **severe hypertension**

(systolic BP > 220 mm Hg or diastolic BP > 110 mm Hg), **hypotension** (systolic BP < 90 mm Hg or a fall in systolic BP > 20 mm Hg from baseline), **ventricular tachycardia** or **sustained supraventricular tachycardia,** and the **development of new WMAs in at least two contiguous segments**.

2. **Pharmacologic SE**
   a. **Dobutamine SE**
      (1) **Dobutamine infusion** is started at 10 μg/kg/min and increased every 3 minutes to 20, 30, and 40 μg/kg/min. If the patient has not reached 85% of APMHR by the end of the 40 μg/kg/min dose, a 3-minute dosage of 50 μg/kg/min may be used. Infusion is begun at lower doses (5 μg/kg/min) if baseline LV function is abnormal and myocardial viability is being sought. Images are digitized at rest and at low dosage (5 to 10 μg/kg/min), pre–peak dosage (30 μg/kg/min), and peak dosage.
      (2) **Atropine** is used as needed to reach target heart rate > 85% of APMHR if dobutamine alone is not effective. Atropine (0.25 to 0.5 mg) is given intravenously every minute, starting at the 40 μg/kg/min dobutamine dose level and continuing until an end point is reached or a total dose of 2 mg is given. Atropine should be used with caution in patients that have glaucoma or benign prostatic hypertrophy. Isometric handgrip may be performed at the peak infusion rate to help achieve target heart rate.
      (3) **Study end points** for dobutamine SE are the same as those used for exercise SE. If 85% APMHR has been achieved without any other end points, it is preferable to complete the protocol to the end of the 40 μg/kg/min infusion to increase the sensitivity of the test.
      (4) **Side effects.** The most serious potential side effect of dobutamine is arrhythmia provocation. However, serious complications (e.g., arrhythmia, MI, and cardiac arrest) are rare, occurring in about 0.3% of studies in a large series of > 5,000 patients. Less serious side effects include tremor, nervousness, and marked hypertensive and hypotensive responses. The most common minor complication is hypotension, which usually responds to supportive therapy including intravenous fluids. A hypotensive response with dobutamine may be caused by ischemia and dynamic outflow tract obstruction or may result from the vasodilatory effect of dobutamine in combination with a small hyperdynamic LV and a low stroke volume.
      (5) **If angina or severe side effects develop**, the effects of dobutamine may be **reversed with intravenous β-blockade** (0.5 to 1 mg/kg esmolol given over 1 minute or 2 to 5 mg/kg metoprolol given every 2 to 5 minutes). Like dobutamine, esmolol has a very short half-life and, therefore, may be preferable.
   b. **Dipyridamole or adenosine SE**
      (1) Patients with hypotension, AV block, or a history of severe bronchospasm **should not undergo** testing with these agents.
      (2) Different protocols of **dipyridamole infusion** have been studied. The protocol recommended by the ASE is a low-dose two-stage infusion. The first stage begins at 0.56 mg/kg dipyridamole over 4 minutes; if no adverse effect or clinical end points are reached, an additional 0.28 mg/kg is infused over 2 minutes. **A high-dose** regimen of 0.84 mg/kg given over 10 minutes has been developed to improve the sensitivity of the test relative to low-dose protocols.
      (3) **Adenosine** is given as a continuous infusion because of its very short half-life. A typical protocol starts at a low dose of 80 μg/kg/min and is increased every 3 minutes by 30 μg/kg/min to a peak dose of 170 to 200 μg/kg/min.
      (4) **Regadenoson** is an adenosine receptor agonist with a 2 to 3-minute half-life, as compared with adenosine's 30-second half-life. Regadenoson is administered as one 0.4-mg dose over 10 seconds.

(5) **Study end points** for dipyridamole or adenosine SE are similar to those used for exercise SE. A notable exception is that patients are not stressed until the APMHR is achieved. Additional end points include third-degree AV block, severe hypotension, and intolerable side effects (e.g., bronchospasm). Symptoms usually start to resolve within 60 seconds after medication administration.

(6) **If hypotension, bradycardia, or bronchospasm occurs**, the effects of dipyridamole, adenosine, and regadenoson can be **reversed with intravenous aminophylline** 25 to 50 mg over 30 to 60 seconds.

D. Imaging techniques. Modern technology allows digital image acquisition of multiple cardiac cycles and side-by-side comparison in a split screen display, enabling easy comparison of regional wall motion at rest and peak stress or after stress. Detailed frame-by-frame evaluation of wall thickening or excursion is possible, which helps in the evaluation of regional myocardial function. Obesity and lung disease remain the primary reasons for poor quality images. **Harmonic imaging** has improved endocardial definition, which can be further optimized with **microbubble contrast agents**.

1. **Contrast echocardiography.** Microbubble contrast agents provide **improved echocardiographic resolution** and allow **real-time assessment of intracardiac blood flow**. These agents are helpful when baseline SE images are suboptimal.
   a. **Intravenous agitated saline** improves visualization of the right atrium and ventricle and enables visualization of intracardiac shunts. However, intravenous agitated saline is not able to cross the pulmonary circulation and opacify the left ventricle.
   b. **Second-generation microbubble contrast agents** such as **Optison** and **Definity** incorporate perfluoropropane gas encased in an albumin-based or phospholipid shell, are more durable, and are able to cross the pulmonary circulation and opacify the left ventricle.
   c. **These agents are well tolerated and have a low complication rate**. After initial concerns about safety, the FDA revised labeling requirements for second-generation contrast agents in 2008 and again in 2011. Patients with pulmonary hypertension or unstable cardiopulmonary conditions including acute coronary syndrome, worsening or unstable heart failure, serious ventricular arrhythmias, or respiratory failure no longer need to have their vital signs and oxygen saturation monitored for 30 minutes after injection. **Absolute contraindications to administration include previous hypersensitivity reaction and fixed right-to-left, bidirectional, or transient right-to-left cardiac shunts.** Intra-arterial injection is contraindicated.
2. **Real-time three-dimensional (3D) echocardiography.** Significant advances have been made in 3D data acquisition without the need for off-line reconstruction. Three-dimensional imaging may shorten the acquisition period of post-exercise images or peak exercise images, allowing improved sensitivity and minimizing the technical strains imposed on the technologist obtaining the images. However, 3D SE is not routine in clinical use and remains under investigation.

V. IMAGE INTERPRETATION

A. Qualitative versus quantitative approach

1. **Interpretation of SE findings is predominantly qualitative.** Visual assessment of LV wall thickening and motion remains the standard method of interpretation of SE but is **subject to interobserver and interinstitutional variability**. Suggestions to optimize interpretation of SE images are outlined in Table 49.2. Each myocardial segment is visually assessed for wall thickening, rather than just wall motion, which may be influenced by myocardial tethering and translation. LV wall motion normally becomes hyperdynamic with stress. Worsening of WMAs or the development of new ones is the hallmark of stress-induced myocardial ischemia. SE responses and interpretation are summarized in Table 49.3.

TABLE 49.2 Suggestions to Optimize Interpretation of Stress Echocardiographic Images

1. Ensure that pre-stress and post-stress images are comparable views
2. Ensure that the apex is not foreshortened, especially in two-chamber views
3. True two-chamber views should not show any of the right ventricle
4. Use ultrasound microbubble contrast agents when resting images are suboptimal
5. Check that digital images are timed to begin at systole. If digital clips include diastole, there is an increased likelihood of calling a false-positive wall motion abnormality
6. Check the heart rate for each post-stress image. If images are obtained after the heart rate has returned toward normal, the sensitivity of the test will be reduced
7. Compare the wall motion of individual segments from rest to stress in the four-screen display to define ischemia and infarction. Then compare segments in the post-stress images to identify differences in contraction and in the development of "hinge points"
8. Confirm any wall motion abnormality in a second view if possible
9. Avoid overcalling ischemia in the basal inferior or basal septal segments
10. Avoid calling a new wall motion abnormality if it is limited to only one myocardial segment; the abnormality should involve at least two contiguous segments

TABLE 49.3 Stress Echocardiographic Responses and Interpretation

Resting or baseline function	Response to low-dose pharmacologic stress	Peak and post-stress function	Interpretation
Normal	Normal	Hyperdynamic	Normal myocardium
Normal	Normal or new WMA	New WMA or lack of hyperdynamic response; LV dilation or decreased EF (with exercise only)	Ischemic myocardium
WMA	No change	No change	Infarcted myocardium
WMA	Improved	Decreased (biphasic response)	Viable (hibernating) myocardium
WMA	No change	Improved	Nonspecific

WMA, wall motion abnormality; LV, left ventricular; EF, ejection fraction.

2. **Quantitative methods** of analysis improve the reproducibility of interpretation and enhance the detection of CAD, particularly by less experienced physicians. However, at this time, **the ASE recommends further validation and simplification of quantitative analysis methods before they can be recommended for routine use**. Examples of quantitative analysis methods include Doppler assessment of global systolic and diastolic function; automated endocardial border detection using integrated backscatter; and tissue Doppler assessment of myocardial displacement, velocity, strain, and strain rate.
   a. **Tissue Doppler assessment** along the long axis using apical views allows quantification of regional longitudinal myocardial function. Tissue Doppler

is thought to be a potentially sensitive marker of subendocardial ischemia because abnormalities in regional contraction occur earlier in longitudinal than radial segments.

b. **Strain rate** is a measure of the speed or velocity of regional myocardial contraction (time from QRS to the onset of regional myocardial relaxation). During dobutamine SE, strain rate increases (interval of time from QRS to myocardial relaxation decreases) in normal hearts and is reduced in areas of myocardial ischemia. The optimal cutoff for strain rate that gives the best sensitivity and specificity has been reported to be an increment of < 0.6 per second. Strain rate imaging is a reliable predictor of coronary stenosis, is **more specific** than visually assessed wall motion scoring, and may allow readers to detect intermediate severity coronary stenosis that produces only subtle WMAs.

B. 17-Segment model. Regional wall motion is assessed using a 17-segment model (Fig. 49.2), with results geographically represented on a circumferential polar plot (Fig. 49.3). A **16-segment model** had previously been utilized for SE, whereas a 17-segment model was utilized for other cardiovascular imaging modalities including magnetic resonance imaging, nuclear scintigraphy, and PET. In 2002, the American Heart Association (AHA) proposed that all tomographic cardiovascular studies utilize the 17-segment model to allow for standardized segmentation and nomenclature. The ASE recommended the 17-segment model in their 2007 SE guidelines.

1. The individual **myocardial segments can be assigned to coronary artery territories**, as illustrated in Figure 49.4. Of note, this approach makes assumptions that are not always correct due to anatomic variability. For instance, the left anterior descending coronary artery does not always supply the entire apex and the posterior wall is not always supplied by the left circumflex coronary artery. The system may also be problematic if multivessel disease is present, in which case the territory with the most ischemia is identified and less severe lesions may not be apparent.
2. Wall motion is **subjectively graded** as normal, mildly hypokinetic, severely hypokinetic, akinetic, or dyskinetic and may be assigned a wall motion score of 1 to 4 (normal, hypokinetic, akinetic, dyskinetic, respectively). Each myocardial segment in the rest and stress images is graded in this manner.

C. Exercise SE

1. A **normal response** to exercise stress includes a global increase in contractility, the development of hyperdynamic wall motion, and a gradual rise in the heart rate. This is manifested by increased wall thickness and increased endocardial excursion with stress.
2. **Resting WMAs** usually indicate prior MI, although regional variability may be seen in diffuse myopathic processes. Resting WMAs may be defined as hypokinetic, akinetic, or dyskinetic. Akinesia and dyskinesia usually indicate transmural infarction, whereas hypokinetic segments may be partially infarcted or viable.
3. An **abnormal response to exercise is defined by the development or worsening of regional myocardial function**. Regional myocardial dysfunction, as **manifested by decreased endocardial excursion and wall thickening**, is **specific for myocardial ischemia**. Decreased excursion alone is less specific and can occur with conduction abnormalities and paced rhythms and in the normal basal inferior myocardial segments.
4. **Adjunctive diagnostic criteria** for a positive SE examination include **LV cavity dilation, a decrease in global systolic function diastolic dysfunction, and new or worsening MR**. However, these adjunctive diagnostic criteria are **more specific for detecting severe CAD and may not be sensitive** for detecting the presence of CAD.
5. **False-positive findings** may occur with left bundle branch block (septal WMA) and right ventricular pacing (apical WMA). A hypertensive response to exercise can cause LV dilation and systolic dysfunction.

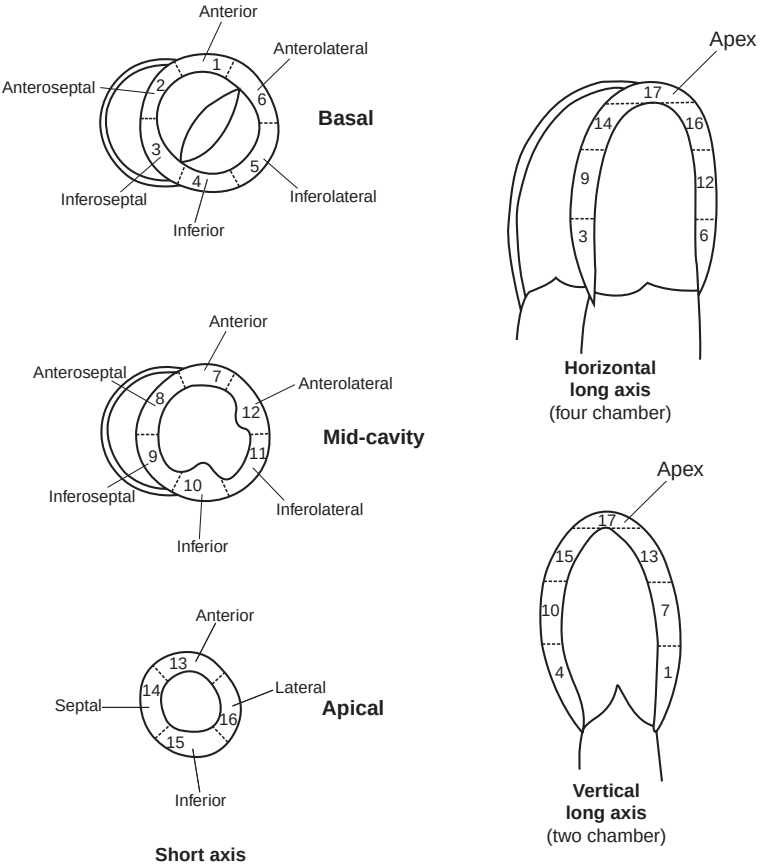

FIGURE 49.2 Diagram of vertical long-axis, horizontal long-axis, and short-axis planes showing the name, location, and anatomic landmarks for selection of the basal (tips of the mitral valve leaflets), mid-cavity (papillary muscles), and apical (beyond papillary muscles but before cavity ends) short-axis slices for the 17-segment system. Reproduced with permission from Cerqueira MD, Weissman NJ, Dilsizian V, et al. Standardized myocardial segmentation and nomenclature for tomographic imaging of the heart: a statement for healthcare professionals from the Cardiac Imaging Committee of the Council on Clinical Cardiology of the American Heart Association. *Circulation.* 2002;105:539–542.

6. **False-negative findings** may occur with delay in capturing post-exercise images or low workload or heart rate response (i.e., inadequate stress). Additional causes of false-positive and false-negative findings are outlined in Table 49.4.

D. Pharmacologic SE. With only a few exceptions, the principles of interpretation of pharmacologic SE findings are similar to those used for exercise echocardiography.

1. The **typical ischemic response to dobutamine** is characterized by normal resting wall motion and an initial **hyperdynamic response at low doses followed by a decline in function at higher doses**. Ischemia may also be identified on the basis of deterioration of normal wall motion without any transient hyperdynamic response.

TABLE 49.4 False-Positive and False-Negative Stress Echocardiographic Test Results

Causes of incorrect stress echocardiographic interpretation	Factors reducing specificity or sensitivity
False-positive results	
LBBB, prior cardiac surgery (e.g., myectomy)	Reduced or abnormal septal excursion with normal septal thickness
Right ventricular pacing	Apical WMA
Nonischemic cardiomyopathy	Regional WMAs (exact cause unknown)
Hypertensive response to exercise (SBP > 220 mm Hg, DBP > 110 mm Hg)	Nonischemic WMAs and/or LV dilation
Overinterpretation	Observer bias may result in a lower threshold for calling a positive study; it is important to be blinded
Basal inferior or septal WMA	Areas most likely to be overcalled because of reduced excursion due to annular tethering effects
Poor image quality	
False-negative results	
Single-vessel disease	More likely to have subtle, rapidly resolving WMA than multivessel disease
Inadequate level of stress (more likely with β-blockers)	Important to stress maximally; reach at least 85% of age-predicted maximum heart rate
LV cavity obliteration (more likely to occur with dobutamine)	Makes segmental wall motion analysis difficult
Left circumflex disease	Lateral wall dropout; more likely to miss ischemia
Delay in capturing images after maximal stress	
Poor image quality	

DBP, diastolic blood pressure; LBBB, left bundle branch block; LV, left ventricular; SBP, systolic blood pressure; WMA, wall motion abnormality.

2. **LV cavity dilation and a decrease in global systolic function are not considered adjunctive diagnostic criteria in dobutamine SE.** The LV cavity may not dilate, and global systolic function may improve with dobutamine despite new WMAs due to severe CAD.
3. Interpretation of results obtained from **dipyridamole or adenosine SE** requires detection of a new or worsening regional WMA during the infusion. There is only a mild increase in cardiac contractility during vasodilator stress.

E. Reproducibility. The person who interprets the images must be well trained to develop an acceptable level of accuracy and must interpret an adequate number of studies on a regular basis to maintain accuracy. Concordance within centers is generally good; however, concordance between different centers may be < 80%, particularly with technically difficult studies and studies of patients with mild CAD.

F. Limitations. The ability to interpret stress echocardiograms is mitigated by the image quality, the presence of arrhythmias, conduction abnormalities, respiratory

interference from hyperventilation, and difficulty in allowing for translational and rotational motion of the heart.

VI. DIAGNOSTIC ACCURACY. The **diagnostic accuracy of SE is superior to exercise electrocardiographic testing alone and similar to radionuclide perfusion techniques**. Reported sensitivities and specificities (using coronary arteriography as the gold standard) vary between studies, depending on the prevalence of disease in the study population, the angiographic definition of significant disease, and the criteria used for a positive test. Clinical factors such as age, cardiac risk factors, and symptoms that influence the pretest likelihood of CAD also influence sensitivity and specificity. For the overall detection of patients with CAD, **sensitivity ranges from 75% to 92%, depending on lesion severity**, and **specificity ranges from 64% to 100%**. As with other imaging methods, the sensitivity is less for the detection of single-vessel disease and greater for the detection of multivessel disease.

A. Exercise SE

1. **Comparison with exercise electrocardiographic testing.** Exercise electrocardiographic testing remains the first-line diagnostic test for CAD. However, **SE has greater diagnostic sensitivity and specificity**, which is predictable on the basis of the earlier occurrence of a systolic WMA before electrocardiographic changes or symptoms in the ischemic cascade (Fig. 49.1). Many factors limit the sensitivity of electrocardiographic testing alone to detect CAD (Table 49.1), and these subgroups should be considered for exercise electrocardiographic testing with an imaging modality.
2. **Comparison with myocardial perfusion scintigraphy**
   - **a.** Myocardial perfusion scintigraphy is based on the detection of a perfusion defect during maximal hyperemia, with reduced perfusion of areas subtended by significant coronary artery stenosis (> 50% stenosis). Perfusion abnormalities occur at an earlier stage in the ischemic cascade than do systolic WMAs, and nuclear scintigraphy should theoretically have a higher sensitivity than SE for CAD.
   - **b.** Studies using **single-photon emission computed tomography (SPECT) myocardial perfusion scintigraphy have demonstrated a sensitivity of > 90%, slightly higher than that for SE.** However, the **specificity of SE is superior to that of SPECT**, especially in cases with LV hypertrophy or left bundle branch block. The overall accuracy of SPECT and SE has been found to be similar in meta-analyses; the superior sensitivity of SPECT is balanced by the superior specificity of SE. The exception may be in women, where SE may be more accurate than SPECT, owing to less artifact from breast attenuation.
   - **c.** SE is **convenient** and **provides information on cardiac structure and function,** and **the results can be interpreted immediately**, with rapid feedback to the patient and referring physician. SE also **avoids exposure to radioactive tracers** and is substantially **less expensive than SPECT**.
   - **d.** SPECT allows for more objective interpretation, with quantification of perfusion abnormalities. It may also be slightly superior for patients on antianginal therapy when it is necessary to induce ischemia. SPECT appears to be more sensitive in the detection of single-vessel disease and may be superior in the detection of ischemia in the setting of resting WMAs, in which the recognition of worsening wall motion may be difficult. SPECT may also be superior in patients that have poor acoustic windows, for example, chronic obstructive pulmonary disease. **Local expertise, cost, exposure to radiation, and patient selection are all important factors in determining which imaging modality to use**.

B. Pharmacologic SE

1. **Dobutamine SE has a sensitivity ranging from 68% to 96% and a specificity of 80% to 85%**, similar to the values for exercise SE. **Vasodilator SE has a sensitivity of 52% to 92% and a specificity of 80% to 100%**. In general, the specificity of vasodilator SE is superior to that of other echocardiographic stress techniques. However, single-vessel disease is more difficult to detect with this technique.

2. **Myocardial perfusion scintigraphy.** Compared with dipyridamole SPECT, dipyridamole SE is believed to be less sensitive but more specific; however, few studies have compared the two tests in the same patients. As with exercise SE, dobutamine SE appears to be slightly less sensitive but more specific than SPECT.

VII. ASSESSMENT OF VIABILITY

A. Myocardial contractility ceases when 20% or more of the transmural thickness is ischemic or infarcted. Dobutamine SE can be used to detect **viable myocardium**, whether stunned or hibernating. **Myocardial stunning** after MI is common, and it is characterized by viable nonischemic noncontracting myocardium. Patients with **chronic ischemia** may experience **myocardial hibernation**. Hibernating myocardium is characterized by viable chronically ischemic noncontracting myocardium.

B. Dobutamine infusion may result in augmentation of regional myocardial function predictive of recovery of function after revascularization. This is important prognostically, as revascularization of hypoperfused but viable myocardium improves survival. A contractile response to dobutamine requires that at least 50% of the myocytes in a given segment are viable.

C. Demonstration of a **biphasic response** to low-dose (5 to 10 μg/kg/min) dobutamine strongly suggests viable myocardium. A biphasic response is present when a **resting WMA improves in response to low-dose dobutamine and decreases in function at peak stress or post-stress**. The initial improvement reflects recruitment of contractile reserve and hence viability. Higher doses lead to subendocardial ischemia and worsened WMA. A biphasic response predicts eventual functional recovery of the myocardium after revascularization. A uniphasic response is less predictive of recovery, and a classic ischemic response is not predictive of the recovery of resting function. Because the biphasic response is the most reliable finding, the preference is to induce ischemia whenever possible by proceeding to maximal stress (40 μg/kg/min).

D. **Myocardial wall thickness** is also an important marker of myocardial viability. When the wall thickness is **< 6 mm**, there is **a low likelihood of recovery of function**.

E. **The negative predictive value of dobutamine SE for determining viability is lower than that of thallium stress-redistribution-reinjection SPECT and Flourodeoxyglucose (FDG)-PET scanning**. However, **the positive predictive value is greater**. Concurrent use of β-blockers can reduce the number of viable segments detected and the sensitivity of testing.

F. **Assessment of myocardial perfusion with echocardiography.** Second-generation microbubble contrast agents are small in diameter and reliably traverse the myocardial microvasculature. The microbubbles are destroyed with ultrasound energy, and the rate of microbubble replenishment represents mean red blood cell velocity and myocardial perfusion. As contrast agents and detection algorithms improve, it is hoped that these techniques will allow real-time, noninvasive assessment of myocardial viability.

VIII. PROGNOSTIC ROLE OF STRESS ECHOCARDIOGRAPHY

A. **Suspected or known chronic CAD.** The **major determinants of prognosis** in patients with chronic CAD are **LV function and the anatomic extent and severity of myocardial ischemia**. SE is an excellent modality for the evaluation of both.

1. **Negative test result.** Perhaps the most important aspect of the prognostic literature is that **a negative test result portends an extremely low risk of subsequent cardiovascular events, as evidenced by an event rate of < 1%/y for the subsequent 4 to 5 years**. However, the risk is slightly higher in patients with diabetes or chronic kidney disease.
2. **Presence of ischemia.** Abnormal findings during SE indicate elevated risk for future cardiac events. Patients at intermediate risk for CAD who have abnormal SE findings have a 1-year cardiac event (i.e., MI, percutaneous coronary intervention, coronary

artery bypass grafting, or death) rate of 10% to 30%. However, this information needs to be integrated with other stress data (i.e., exercise capacity, hemodynamic responses to exercise, heart rate recovery, chronotropic index, Duke treadmill score, and the type and extent of WMA). Electrocardiographic changes and hypotension are relatively insensitive measures of ischemia during dobutamine SE. However, from the prognostic standpoint, the development of echocardiographic evidence of ischemia with dobutamine is analogous to its development during exercise.

3. **Presence of nonviable myocardium.** In patients with the same pretest probability of disease, those with evidence of nonviable myocardium during SE have higher rates of cardiac events than those with normal SE findings, but they have fewer events than those with evidence of ischemia during SE. Heart failure is a more common end point among the group of patients with nonviable myocardium.

B. Post–myocardial infarction. High-risk patients after acute MI are routinely identified by age, recurrent angina, LV failure, and shock. In addition, echocardiographic features predicting outcome after MI include LV ejection fraction, the extent of resting WMAs, inducible ischemia (detected as stress-induced WMA), and the amount of viable myocardium. All of these may be identified using SE, and several large studies (most with pharmacologic stressors) have gathered prognostic data using SE in patients post-MI.

C. Noncardiac surgery

1. Preoperative evaluation studies have been predominantly conducted with pharmacologic stress agents, primarily dobutamine. However, exercise SE should be considered if possible. A low ischemic threshold during stress (ischemia at heart rate < 70% APMHR) is the strongest predictor of perioperative cardiac events.
2. The predictive value of a positive test ranges from 7% to 25% for hard events (i.e., MI or death). The negative predictive value ranges from 93% to 100%. Only a few studies have compared SE and SPECT for the prediction of perioperative cardiac events. A meta-analysis concluded that the tests had comparable levels of accuracy, but the cost features weighted in favor of SE.

D. Cardiac transplantation. Transplant vasculopathy is a major cause of mortality after cardiac transplantation. Despite some promising data, SE appears to lack both sufficient sensitivity and specificity to be a viable alternative to routine angiography as a screening method.

E. Reading beyond wall motion. Important prognostic information can be obtained beyond traditional wall motion analysis. Ischemic heart disease may cause subclinical **diastolic dysfunction**. **Left atrial enlargement** correlates with the chronicity and severity of diastolic dysfunction. A normal resting left atrial volume index (< 28 mL/m^2) is strongly predictive of a normal stress echocardiogram. **Right ventricular dysfunction** is a significant predictor of events, independent of LV ischemia or ejection fraction.

IX. DIASTOLIC STRESS ECHOCARDIOGRAPHY

A. In many patients, "diastolic" heart failure is the dominant form of dysfunction, without any detectable systolic dysfunction at rest or during stress. The **transmitral peak early diastolic velocity (E)** and the **mitral annulus early diastolic velocity (e′)** are utilized to assess the diastolic dysfunction. In the presence of normal LV systolic function and volumes, an **E/e′ ratio > 15 suggests elevated LV filling pressure and diastolic dysfunction**, whereas a ratio < 8 excludes diastolic dysfunction. The primary utility of diastolic SE is to evaluate patients in whom diastolic dysfunction is suspected but the resting echocardiogram is indeterminate (i.e., E/e′ 8 to 15). Assessment for diastolic dysfunction should be completed during routine SE, as its presence and severity add to the negative prognostic value of resting or stress-induced systolic dysfunction.

B. Exercise or adrenergic stress normally results in improved myocardial lusitropy (relaxation) to allow for better filling in a shorter amount of time. The tachycardia associated with exercise results in an abbreviated diastolic filling period and an increase in the transmitral peak E velocity. In healthy patients, both the transmitral

peak E velocity and the mitral annulus early diastolic velocity increase with exercise, and the E/é ratio is not changed. However, **in patients with diastolic dysfunction, the mitral annulus early diastolic velocity is minimally affected by the change in preload caused by exercise and the E/é ratio increases**.

C. Assessment of diastolic dysfunction can be difficult at rest and is even more so with stress. Exercise SE is optimally performed using **supine bicycle ergometry**, as it allows for the acquisition of Doppler recordings during exercise. However, evaluation is routinely performed using treadmill exercise or dobutamine. Tachycardia may result in fusion of the transmitral E and A velocities at peak stress, making the tracings impossible to interpret. Therefore, Doppler assessment of the mitral inflow velocities should be assessed at rest, during exercise, and in recovery if possible.

X. STRESS ECHOCARDIOGRAPHY IN NONISCHEMIC CARDIAC DISEASE.

SE can be used to evaluate the functional significance of a variety of valvular lesions as well as hypertrophic cardiomyopathy. SE is especially helpful when there is a discrepancy between clinical symptoms and the assessment of valve severity at rest.

A. Aortic stenosis

1. Exercise testing is contraindicated (ACC/AHA class III recommendation) in patients with symptomatic AS. In asymptomatic patients, exercise testing may be considered (ACC/AHA class IIb recommendation) to elicit exercise-induced symptoms and abnormal BP responses.
2. Dobutamine SE is reasonable (ACC/AHA class IIa recommendation) in the diagnostic evaluation of patients with **low-flow/low-gradient AS**, defined as Doppler-derived aortic valve area < 1 cm^2 and mean gradients < 30 mm Hg. In these patients, **dobutamine is used to assess both the severity of AS and the presence of contractile reserve**.
3. In severe AS, low-dose (20 μg/kg/min) dobutamine infusion results in increased cardiac output with a parallel rise in the mean transvalvular gradient. Provided the calculated aortic valve area remains < 1 cm^2, **an increase in the mean transvalvular gradient to a value > 30 mm Hg or velocity > 3.5 m/s is consistent with severe AS**. If dobutamine infusion results in an increase in the valve area (typically to > 1 cm^2) with little change in the gradient, it is likely that LV dysfunction rather than AS is the critical problem, and aortic valve replacement is unlikely to be beneficial.
4. Dobutamine SE is also used to identify **contractile reserve** in patients with low-flow/low-gradient AS. Contractile reserve is defined as > 20% increase in stroke volume with dobutamine infusion. Lack of contractile reserve is associated with poorer prognosis with either medical or surgical therapy.

B. Mitral regurgitation. In asymptomatic patients with severe MR, exercise SE is reasonable (AHA/ACC class IIa recommendation) to assess exercise tolerance and the effects of exercise on pulmonary artery pressure and severity of MR. SE can help predict latent LV dysfunction in patients with normal baseline LV systolic function, severe MR, and minimal or no symptoms. An increase in the LV cavity size or decrease in LV ejection fraction at peak stress suggests latent LV dysfunction and an increased risk of LV dysfunction after valve repair.

C. Mitral stenosis. Exercise SE should be performed (ACC/AHA class I recommendation) to assess the hemodynamic response of the mean gradient and pulmonary artery pressure in patients with mitral stenosis when there is a discrepancy among resting Doppler echocardiographic findings, clinical findings, symptoms, and signs. An increase in the mean transmitral pressure gradient > 15 mm Hg and pulmonary artery systolic pressure > 60 mm Hg are indications to consider percutaneous valvotomy.

D. Hypertrophic cardiomyopathy. In patients with hypertrophic cardiomyopathy and high resting left ventricular outflow tract (LVOT) gradients, routine exercise testing is not performed owing to increased risks of arrhythmias and hypotension. Exercise SE provides valuable information, including exercise hemodynamics and the inducibility of LVOT, worsening of mitral regurgitation, and provocable

gradients in patients that are asymptomatic at rest. Although these patients may have only mild to moderately elevated resting LVOT gradients, using SE to identify elevated provocable gradients may help explain their exertional symptoms and quantify their exercise tolerance.

Testing for Viable Myocardium

I. INTRODUCTION. Patients with left ventricular (LV) dysfunction secondary to coronary artery disease (CAD) have significant morbidity and mortality. Given the prognostic implications of poor ventricular function, it is imperative to identify any reversible myocardial dysfunction that may improve with revascularization.

II. DEFINITIONS

A. Viable myocardium is defined as myocardium that demonstrates abnormal function at rest and improves with revascularization.

1. From a pathophysiologic standpoint, chronically reduced perfusion leads to cellular changes that ultimately cause irreversible myocyte dysfunction.
2. Biopsies of myocardium reveal a spectrum of fibrosis and sarcomere loss that correlates with the likelihood of recovery of function. Several studies have found that once fibrosis is found in more than 35% of the myocardium, the likelihood of recovery of function is low.
3. **Stunning** refers to transient myocardial dysfunction, which is often caused by abrupt cessation of flow typical of an acute coronary occlusion.
4. Myocardial **scar** from cellular necrosis is irreversible and does not improve with revascularization.

B. Hibernation occurs when viable myocardium has altered its metabolism and thus reduced its contractile function as a mechanism to cope with chronically inadequate blood supply (chronic stable angina) or repetitive ischemic injury.

III. CLINICAL PRESENTATION. Ischemia, stunning, hibernation, scarring, and normal myocardium may coexist in the same patient. Unfortunately, clinical symptoms are unreliable in determining if a patient has viable myocardium, as often patients experience no symptoms in the face of considerable LV dysfunction and ischemia.

IV. TREATMENT OPTIONS. It has been demonstrated that revascularization of viable myocardium improves quality of life and survival. As medical and surgical technology improves in the field of cardiovascular medicine, it is important to accurately identify patients who will benefit from revascularization.

A. Thrombolytic therapy or emergency percutaneous revascularization is used in the setting of an acute thrombotic occlusion to restore normal blood flow and hopefully to minimize cellular damage.

B. Revascularization procedures, such as coronary artery bypass grafting and percutaneous transluminal coronary angioplasty, may improve regional and global LV systolic function caused by significant CAD. The presence and extent of viable myocardium have been demonstrated as a marker for patients who will do significantly better with revascularization than with conventional medical care.

C. It is notable that patients with nonviable myocardium have similar outcomes with medical therapy as with revascularization.

D. Because not all patients benefit from revascularization procedures, the identification and referral of patients who will derive benefit are important to reduce costs and morbidity with the associated procedures. The goal, therefore, is to reliably identify patients who will benefit from revascularization and subsequently refer these patients for appropriate intervention.

V. TECHNIQUES TO ASSESS VIABILITY

(Fig. 50.1). Assessment of myocardial viability is indicated in patients with CAD and resting LV dysfunction who are eligible for revascularization. Coronary angiograms provide information about anatomy and feasibility of revascularization but do not predict recovery of function. Resting echocardiography provides information regarding overall LV function and segmental wall motion abnormalities but does not address recovery of function with revascularization techniques. Single photon nuclear imaging techniques (single photon emission computed tomography, SPECT), positron emission tomography (PET) with a metabolic agent, dobutamine echocardiography, contrast echocardiography, and, more recently, delayed-enhancement magnetic resonance imaging (MRI) have been identified as techniques that can distinguish viable myocardium from nonviable myocardium. Each technique exploits a separate property of dysfunctional myocardium to determine the potential for recovery of function after revascularization. The test that is used often depends on the strengths and preference of each medical center, although an approach based on the individual patient would be preferable.

A. Single photon emission computed tomography. SPECT is the most common technique used in the United States to identify viable myocardium. This technique has been successful because thallium 201 and technetium 99m radiopharmaceuticals act as perfusion agents that are only taken up by viable tissue. The long half-lives of these agents allow for regional distribution, which makes them feasible to use in medical centers without a generator or cyclotron. In addition, stress SPECT protocols (exercise or pharmacologic) are frequently used to assess for ischemia, which makes this technique cost-effective in a busy clinical center. Routine studies also include gated imaging analyses that provide further information regarding LV function and wall motion assessment, which are important in the evaluation of viability.

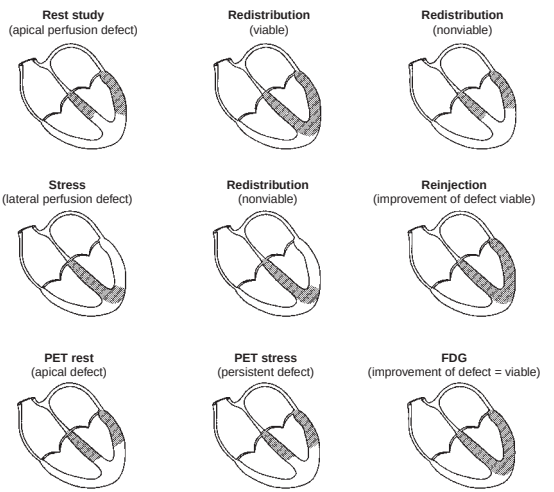

FIGURE 50.1 Viability testing.

FDG, 18F-fluorodeoxyglucose scanning

1. **Thallium 201** is a potassium analogue that utilizes the Na^+/K^+-ATPase active cellular transport system for concentration in cells and relies on intact cells. This characteristic of thallium makes it useful for the identification of viable cells as opposed to necrotic cells. Uptake of thallium is also dependent on regional myocardial perfusion.
   a. Thallium 201 has a relatively long half-life (73 hours), which means that a small dose (2 to 4 mCi) must be used. It emits x-rays from 68 to 80 keV (94% abundant) and γ-rays at 135 and 167 keV (10% abundant). There is a linear relationship between blood flow and uptake of thallium at rest, which is maintained with exercise making it as a reliable indicator of perfusion.
   b. **Redistribution** of thallium between the intracellular and intravascular spaces begins to occur after the first pass of thallium. It is recognized that with time, initial defects on thallium imaging improve. This is thought to be related to the accumulation of tracer in hypoperfused areas over time as well as rapid washout in normally perfused areas. On the basis of these principles, several protocols have been used to identify viable myocardium.
      (1) **Rest/redistribution thallium** imaging involves imaging 30 to 60 minutes after an initial injection followed by reimaging 4 hours later. Defects on the initial images that improve in 4 hours are considered to represent areas of viable myocardium. This protocol does not address ischemia and has been proven to be less sensitive for detecting viable myocardium than other protocols using thallium or PET with 18F-fluorodeoxyglucose (FDG).
      (2) **Stress/redistribution** imaging uses pharmacologic or exercise-induced stress with subsequent thallium injection and imaging, immediately followed by reimaging 4 hours later. Myocardium that is not perfused with stress or rest is considered to be scar. Myocardium that has a defect with stress but that improves on rest images is considered to be ischemic and viable. This protocol can identify ischemic viable myocardium, but it also shows lower sensitivity than other protocols, as many of the defects that do not improve at 4 hours may contain viable tissue. Imaging 24 hours after stress in a search for "late redistribution" improves sensitivity in the detection of viability but has low specificity and may be inconvenient. However, blood levels of thallium 201 may still be too low to be redistributed and picked up by viable myocardium. This led to the development of reinjection protocols mentioned later in this chapter.
      (3) **Stress/redistribution/reinjection** protocols involve the reinjection of 1 mCi of thallium with subsequent reimaging of the patient. This protocol is designed to increase the sensitivity by increasing the blood levels of thallium. It was shown that 50% to 70% of "scarred myocardium" after 4-hour redistribution imaging was actually viable, as demonstrated by this technique. Typically, reinjection of thallium and repeated imaging is performed immediately after the redistribution images or several hours after the initial stress images, followed by redistribution imaging 18 to 24 hours later. Sensitivity does not differ significantly between these two techniques. Scar is considered to be myocardium that has a defect on the stress images and does not improve upon reinjection and reimaging. Viable myocardium is indicated by uptake of tracer on reinjection in segments where no uptake occurred with stress.
2. **Technetium 99m–labeled radiopharmaceuticals** rely on mitochondrial function, sarcolemmal integrity, and intact energy production pathways for cellular accumulation.
   a. **Technetium characteristics.** Technetium 99m compounds have a shorter half-life (6 hours) than thallium, which allows for the administration of

larger doses (10 to 30 mCi), depending on the compound. Technetium 99m emits γ-rays at 140 keV. The commonly used agents include Tc 99m sestamibi, Tc 99m tetrofosmin, Tc 99m teboroxime, Tc 99m furifosmin, and Tc 99m NOET (bis(*N*-ethoxy, *N*-ethyl dithiocarbamato)nitrido).

b. Redistribution of technetium compounds is significantly less than that for thallium, making it relatively unhelpful as an aid in detecting viability.

3. Quantitation of SPECT imaging has been found to be a more accurate method to identify high- and low-risk populations than qualitative analysis. Quantification of perfusion has been proven to be an accurate predictor of recovery of function and superior to qualitative measurements at providing clinically useful information about future risk.

4. Diagnostic accuracy

a. Multiple studies have been performed comparing the various thallium protocols versus PET with FDG as the gold standard. Typically, sensitivity improves as one goes from redistribution to reinjection/redistribution and finally quantitative analysis of reinjection/redistribution. Semiquantitative analysis of stress/redistribution/reinjection has good concordance with PET.

b. In the prediction of functional improvement after revascularization, rest/redistribution thallium scans (sensitivity 90% and specificity 54%) and stress/redistribution/reinjection thallium scans (sensitivity 86% and specificity 47%) have been found to be less reliable. Regions that demonstrate < 60% regional thallium uptake on redistribution have a very low chance of recovery.

c. Unfortunately, attenuation and patient artifact frequently make SPECT thallium images difficult to interpret. In addition, methods for quantification have not been standardized across medical centers.

d. Quantification of sestamibi has compared favorably with that of thallium, with redistribution in the prediction of recovery of function after revascularization. Several other technetium compounds used for the assessment of viability have been tested (Tc 99m tetrofosmin, Tc 99m teboroxime, Tc 99m furifosmin, and Tc 99m NOET). None of these other agents has had significant use except for ^{99m}Tc-NOET, which has similar redistribution kinetics to that of thallium and may be a useful agent in the future. Sestamibi has a limited role in viability assessment owing to its cost.

B. PET in conjunction with a metabolic agent, usually FDG, has been considered the gold standard for assessment of myocardial viability. PET uses positron-emitting isotopes capable of releasing two high-energy (511 keV) photons at an angle of 180° from each other. The PET camera can detect these higher energy rays through coincidence counting. As a result, PET provides higher temporal and spatial resolution than SPECT, which translates into a higher quality image. Additional features of PET include quantification of the following:

1. Practical issues, including the cost of a PET camera and the short half-life of the several of the cyclotron-produced radiotracers, limit the use of PET to specialized medical centers.

2. Unlike SPECT, PET uses separate agents to measure perfusion and viability.

3. Perfusion agents commonly used in PET imaging include rubidium 82, nitrogen 13 ammonia, and oxygen 15 water.

a. Rubidium 82 is a generator-produced potassium analogue that relies on intact cellular functioning for its uptake and distribution. Hence, rubidium 82 is washed out of necrotic cells and trapped in viable cells.

b. Nitrogen 13 ammonia is cyclotron-produced radiotracer and also relies on intact cellular functioning for its uptake and distribution. This is the most commonly used perfusion agent in PET, and it can be used to quantify blood flow and assess for myocardial viability.

c. **Oxygen 15 water** is a freely diffusible agent that has been used to quantify blood flow. Blood flow < 0.25 mL/g/min within a region of myocardium is correlated with regions of scar. Unfortunately, intermediate blood flow ranges have not been reliable in predicting recovery of function, which makes this technology less useful for quantifying viability. Oxygen 15 water has also been used to create a perfusable tissue index that has been shown to improve the accuracy in the assessment of viable myocardium but has not been utilized by many centers.

4. **Metabolic agents** used in PET include FDG, carbon 11 acetate, and carbon 11 palmitate. **FDG** (cyclotron-produced) has the most clinical data to support its use. It has a long half-life, which makes its transportation to regional medical centers more practical. FDG is taken up by viable cells and then phosphorylated so that it cannot be metabolized further. This effectively traps FDG in the myocardium. In normal myocardium, free fatty acids are preferentially used. During periods of ischemia, metabolism is altered so that primarily glucose is utilized. The limitation of FDG has been in diabetics with impaired cellular uptake of glucose, where approximately 10% of studies are difficult to interpret owing to poor tracer uptake.
5. The combination of perfusion and metabolic tracers gives three possible interpretations:
   a. Normal perfusion is indicative of viability on its own and does not require specific assessment of metabolism.
   b. Reduced perfusion in myocardial segments with intact metabolic function as evidenced by the uptake of FDG is termed flow–metabolism mismatch and is indicative of hibernating, viable myocardium (Fig. 50.2).
   c. Impaired FDG uptake combined with reduced perfusion (flow–metabolism match) is indicative of myocardial scar (Fig. 50.2).
6. **Diagnostic accuracy.** PET-FDG and cardiac MRI are considered the most reliable tests of myocardial viability. Image quality with PET is better than that with SPECT, and myocardial metabolism may be assessed directly with FDG. The sensitivity and specificity of PET in predicting functional improvement in myocardial segments after revascularization are 71% to 100% and 38% to 91%,

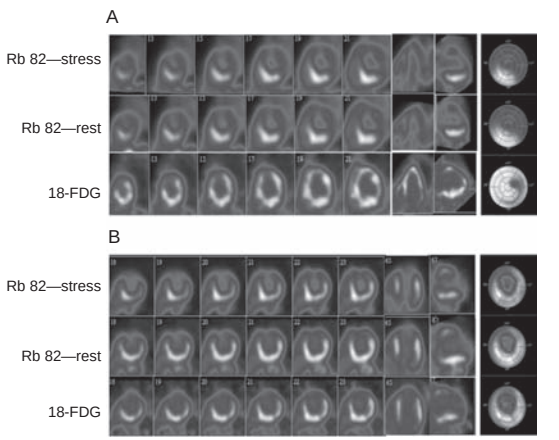

FIGURE 50.2 Rubidium PET followed by FDG PET: Patient **A** showing metabolism mismatch and is indicative of hibernating, viable myocardium. Patient **B** showing impaired FDG uptake combined with reduced perfusion (flow–metabolism match) is indicative of myocardial scar.

respectively. PET has been shown to predict low surgical risk in patients with LV dysfunction and viability, improvement in exercise capacity with revascularization, and benefit from revascularization over medical therapy.

C. Dobutamine echocardiography has proven to be a reliable predictor of recovery of function after myocardial revascularization.

1. **Protocol.** Viability studies with dobutamine echocardiography use low doses of dobutamine starting as low as 5 μg/kg/min and slowly increasing the dose at 3-minute intervals up to 40 μg/kg/min for the development of other end points, such as target heart rate and symptoms. Imaging is performed throughout the study at each level of dobutamine infusion. Accurate, consistent results are contingent on the acquisition of excellent images for interpretation and on an experienced reader to interpret the study.
2. **Pathophysiology.** Dobutamine echocardiography exploits the inotropic effect of dobutamine at low doses on viable myocardium. This improvement in function and wall thickening is referred to as contractile reserve. In viable myocardium, with increasing doses of dobutamine, myocardial oxygen consumption increases, and ischemia develops with worsening of wall motion abnormalities. Therefore, in viable myocardium a segment with reduction in wall thickening at rest demonstrates an improvement or even normalization of wall thickening upon infusion of low-dose dobutamine. At higher doses of dobutamine, wall thickening deteriorates and may revert to the baseline level or may be even more severely reduced than at baseline. This **biphasic response** during dobutamine echocardiography is thought to be the most specific sign of dobutamine echocardiography for predicting improvement in function in myocardial segments with revascularization and indicates segments with underperfused but viable tissue. Myocardial segments with impaired contraction at rest that do not improve upon infusion of dobutamine are considered to be scarred (nonviable). Those segments with impaired thickening at rest that show improvement in thickening upon dobutamine infusion but that do not show deterioration in thickening at higher doses of dobutamine infusion are considered to have a **uniphasic** response. A uniphasic response is seen in the setting of myocardial damage with subsequent reperfusion (i.e., an open artery without a flow-limiting stenosis) and is much less predictive of improvement after revascularization.
3. **Diagnostic accuracy.** Dobutamine echocardiography has good specificity for the detection of viability. Part of the high specificity is derived from the fact that echocardiography is the most common method of assessing postoperative improvement. In addition, improvement of hypocontractile myocardium in response to low-dose dobutamine is the defined end point that revascularization is trying to achieve, although it is less sensitive than cellular metabolic function as a marker of viability. Sensitivity and specificity for recovery of function are 84% and 81%, respectively.
4. **Limitations** of dobutamine echocardiography include difficulty in obtaining images in patients with poor ultrasound windows, interobserver variability, even among expert readers, provocation of ventricular arrhythmias with testing, and reduced sensitivity in comparison with nuclear imaging.

D. Cardiac MRI. Delayed-enhancement MRI using gadolinium-based agents given intravenously (0.2 mmol/kg) has been shown to reliably distinguish infarcted from viable myocardium. Unlike SPECT-based techniques, MRI poses no risk of ionizing radiation exposure.

1. **Pathophysiology.** Gadolinium-based contrast agents are extracellular compounds that, when injected intravenously, pass quickly through normal areas of myocardium. In scarred tissue, the interstitial space between collagen fibers is larger than in normal myocardium, causing a delayed "wash-in" of gadolinium contrast. The gadolinium then remains trapped in the scarred tissue, causing

a longer "washout" of gadolinium from the infarcted or fibrotic myocardium. Delayed-enhancement MRI takes advantage of this delayed wash-in and washout of gadolinium to detect fibrotic or scarred myocardium, which appear as hyperenhanced (bright) areas of myocardium on images taken 10 to 20 minutes after contrast injection.

2. In patients with ischemic heart disease, scarred or nonviable myocardium occurs in a coronary artery distribution. Scarring typically begins at the subendocardial surface and extends outward at a variable distance toward the epicardium. The **transmural extent of hyperenhancement** on delayed-enhancement images is then used to determine the viability of each myocardial segment. Segments with **0% to 25% transmural extent of hyperenhancement represent viable tissue** with mostly normal myocardium and minimal fibrosis. **Segments with 75% to 100% transmural extent of hyperenhancement represent scarred, nonviable myocardium**. Segments with 25% to 75% transmural extent are said to have intermediate viability, although in clinical practice the amount of viable tissue in adjacent myocardium is often taken into account when classifying these intermediate segments. Finally, the amount of hyperenhancement within a region can be correlated with segmental wall function and rest/stress perfusion to determine ischemia and viability.
3. The absence of significant hyperenhancement has been shown to correlate well with improvement in function, whereas hyperenhancement of more than 75% has been correlated with irreversible injury. Of interest to note, the mean transmural extent of hyperenhancement that predicted irreversibility was 41 ± 14% by MRI, which correlates with a biopsy series wherein 35% fibrosis predicted similar lack of improvement after revascularization (Fig. 50.3).
4. **Diagnostic accuracy.** Studies comparing different imaging modalities for viability have shown superior sensitivity and specificity for MRI compared with SPECT and similar sensitivity with slightly improved specificity compared with PET. The main advantage of MRI is its ability to delineate the transmural extent of infarction, owing to its better spatial and contrast resolution. The pattern of hyperenhancement on MRI can also be used to identify nonischemic causes of cardiomyopathy.
5. **Limitations.** MRI is generally contraindicated in patients with implanted ferromagnetic objects (e.g., pacemakers, implantable cardioverter–defibrillators [ICDs], and ferromagnetic cerebral aneurysm clips), although some centers will image selected patients with permanent pacemakers/ICDs under careful electrophysiologic evaluation. Gadolinium is contraindicated in patients with chronic kidney disease (glomerular filtration rate < 30 mL/min), particularly in those

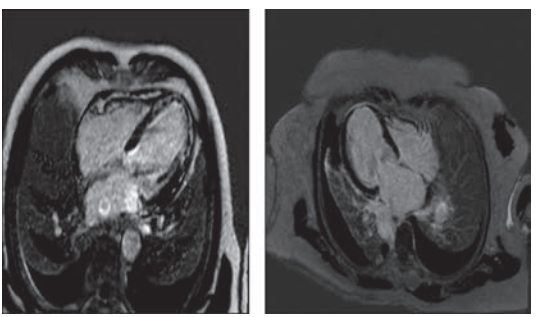

FIGURE 50.3 Late gadolinium-enhanced MRI: Both patients **A** and **B** have extensive akinesia in LAD territory; however, patient **A** has more extensive scar (> 50% in multiple segments) than patient **B** and is less likely to have LV function recovery post revascularization.

undergoing dialysis, owing to a small but important risk of nephrogenic systemic fibrosis (see Chapter 51). Finally, image quality may be compromised in patients unable to comply with breath-holding for the study (10 to 12 seconds each) and severe claustrophobia, as well as in patients with arrhythmias or frequent ectopy.

VI. CHOICE OF TECHNIQUE. Cost, clinical expertise, and access to radioisotopes are all issues that affect the appropriateness of each imaging technique. SPECT thallium and dobutamine echocardiography are significantly less expensive than PET and MRI, but they require significant clinical experience for appropriate data collection and interpretation. Both PET and cardiac MRI are robust techniques for the assessment of viability, but their use may be limited due to cost and availability, and, for MRI, the presence of patient's contraindications to MRI. The choice of technique is ultimately determined by local expertise and access to the appropriate technology. The recently published STICH (Surgical Treatment for Ischemic Heart Failure) viability trial failed to demonstrate a significant interaction between myocardial viability and medical versus surgical treatment with respect to mortality. These findings are most likely explained by improved modern-day medical therapy; however, there were several limitations of this trial which should be noted. Although the main STICH trial was a randomized controlled trial, the STICH viability substudy was not randomized. It was an observational study on almost half of all the main STICH trial patients who managed to get a viability study. Furthermore, viability testing in the trial was performed by using SPECT, thallium, and dobutamine only, and more robust techniques of cardiac MRI and FDG PET were not used.

VII. WHO SHOULD GET A VIABILITY TEST? Patients who are most likely to benefit from viability testing (preferably by cardiac MRI or FDG PET) are those with high operative risk, where presence or absence of viability may influence the management strategy. Viability can also be useful in choosing the optimal revascularization strategy (PCI vs. CABG) in patients with multivessel disease. Viability testing should not be performed in patients where it is unlikely to change management, such as in a young patient with angina, good distal target vessels, and minimal comorbidities.

CHAPTER 51

João L. Cavalcante

Cardiovascular Magnetic Resonance Imaging

I. INTRODUCTION. Cardiovascular magnetic resonance imaging (CMRI) has undergone rapid developments over the last two decades and is now an important imaging technique of the heart and great vessels. Advantages of CMRI include its large field of view, high spatial and temporal resolution, and ability to do tissue characterization. In contrast to nuclear imaging and cardiac computed tomography (CT), magnetic resonance imaging (MRI) does not involve exposure to ionizing radiation. Applications of CMRI include acquisition of anatomic-quality still and cine images of the heart and great vessels in multiple planes, precise measurement of cardiac chamber volume and function, assessment of myocardial perfusion and fibrosis, quantification of blood velocity and flow, and noninvasive magnetic resonance angiography (MRA). As CMRI is not a "push-button" technique, clear communication between the ordering physician and the imaging staff is important, indicating the reason for the CMRI examination so that adequate pulse sequences and imaging planes are obtained aiming to answer the desired clinical question.

II. INDICATIONS. Common indications and components of the CMRI evaluation are listed in Table 51.1.

III. CONTRAINDICATIONS. Contraindications to CMRI are listed in Table 51.2.

IV. BASICS OF CARDIAC MRI

A. MRI Physics. Hydrogen is the most abundant atom in the body, and it is the excitation of hydrogen nuclei, often referred to as protons, that forms the basis for clinical MRI. Atoms behave like tiny bar magnets, aligning parallel to an external magnetic field while wobbling about the magnetic field at a certain frequency (precessional frequency) that creates the longitudinal magnetization. Application of a short radiofrequency (RF) pulse with the same precessional frequency as that of the atomic nucleus will cause excitation or resonance of the nucleus, temporarily changing its alignment within the magnetic field (transverse magnetization). However, this is an unstable state of higher energy. As the RF pulse is switched off, the spins quickly return to their resting state, i.e., aligned with the field, as this is energetically

TABLE 51.1 Cardiovascular Magnetic Resonance Imaging Indications and Applications

Indication(s)	Applications
Aortic disease	Aortic aneurysm morphology and size; acute aortic pathology (dissection, intramural hematoma, penetrating ulcer); coarctation of the aorta; branch vessel disease; evidence of vasculitis; postoperative graft stenosis, infection, or leak; assessment for aortic regurgitation or other associated pathologies
Ischemic heart disease	Ventricular volumes and function; myocardial scar and viability; quantification of mitral regurgitation; assessment for LV aneurysm, thrombus, VSD, and other complications
Nonischemic cardiomyopathies	Ventricular volumes and function; myocardial wall thickness; LV outflow tract obstruction in hypertrophic cardiomyopathy; presence and patterns of myocardial scar/fibrosis; assessment for myocardial iron deposition in suspected hemochromatosis; quantification of mitral regurgitation; evaluation for ARVD in patients with ventricular arrhythmias or syncope
Pericardial disease	Pericardial effusion; pericardial thickening with or without calcification; pericardial tethering; signs of constrictive physiology including conical/tubular deformity of the ventricles, diastolic septal bounce, early cessation of diastolic filling, and dilated IVC
Congenital heart disease	Anatomic definition; ventricular volume and function; valve morphology and function; shunt calculation; assessment for anomalous origin of the coronary arteries; anomalies of the aorta, pulmonary arteries, and systemic and pulmonary veins
Valvular heart disease	Valve morphology; regurgitation and/or stenosis etiology and severity; ventricular size and function
Cardiac masses	Size and extent of mass; tissue characterization
Pulmonary veins	Pulmonary vein anatomy and stenosis; cardiac anatomy and function

ARVD, arrhythmogenic right ventricular dysplasia; IVC, inferior vena cava; LV, left ventricular; VSD, ventricular septal defect.

TABLE 51.2 Contraindications to Cardiovascular Magnetic Resonance Imaging

Specific devices	Special issues
Cerebral aneurysm clips	Certain cerebral aneurysm clips pose a danger due to potential for displacement when exposed to a magnetic field. Aneurysm clips classified as "nonferromagnetic" or "weakly ferromagnetic" are safe.
Cardiac pacemakers and ICDs	The presence of a pacemaker/defibrillator is a strong relative contraindication to MRI owing to several potential problems, including (1) movement, (2) malfunction, (3) heating induced in the leads, and (4) current induced in the leads. In addition, artifact from the leads will often cause significant image degradation.
	FDA has recently approved the first MRI-safe pacing system (Revo MRI by Medtronic, Inc.) that allows patients to undergo, for example, brain and knee MRI scans. Currently it is not safe for the area of coverage to include the chest, although ongoing work is being done toward that goal.
Cardiovascular catheters	Catheters with conductive metallic components (e.g., pulmonary artery catheters) have the potential for excessive heating. Hence patients with such devices should not undergo MRI.
Cochlear implants and hearing aids	Most types of implants employ a strong magnet or are electronically activated. Consequently, MRI is contraindicated because of potential injury or damage to the function of these implants. External hearing aids can and should be removed before the MRI procedure.
Intravascular coils, stents, and filters	These devices typically become incorporated securely into the vessel wall within 6–8 wk after implantation; hence, most are considered MRI safe. However, specific information on the type of device should be obtained before MRI is planned (www.mrisafety.com). Intracoronary stents have been shown to be safe during MRI, even when performed on the day of implantation, although many stent manufacturers recommend waiting 6–8 wk.
ECG electrodes	MR-safe ECG electrodes are strongly recommended to ensure patient safety and proper ECG recording.
Foley catheters	Certain Foley catheters with temperature sensors have the potential for excessive heating. They are generally safe if positioned properly and disconnected from the temperature monitor during MRI.
Heart valve prostheses	All types of heart valve prostheses have been shown to be safe during MRI. However, prosthetic material may lead to image artifacts.
Metallic foreign bodies	All patients with a history of injury with metallic foreign bodies such as a bullet or shrapnel should be thoroughly evaluated, as serious injury may result from movement or dislodgement of the foreign body.
Metallic cardiac occluders (e.g., management of PDA, ASD, or VSD)	MRI is safe for nonferromagnetic devices immediately after implant. Weakly ferromagnetic devices are safe from approximately 6–8 wk after placement, unless there is concern about retention of the device.
Retained epicardial pacing wires	MRI in patients with retained epicardial pacing wires after cardiac surgery appears safe. Retained transvenous pacing wires are a contraindication to MRI.

ASD, atrial septal defect; ECG, electrocardiogram; ICD, implantable cardioverter–defibrillator; MR, magnetic resonance; MRI, magnetic resonance imaging; PDA, patent ductus arteriosus; VSD, ventricular septal defect.

the most favorable situation. The newly established transverse magnetization starts to disappear (a process called transversal relaxation), and the longitudinal magnetization grows back to its original size (a process called longitudinal relaxation). During this process, an RF signal is generated, which can be captured by the receiving coil and readily measured. This process constitutes the underlying principle of MRI.

The signal generated by an excited proton is dependent on its molecular environment, such that the magnetic resonance (MR) signal from a hydrogen atom in blood can be discriminated from the MR signal from a hydrogen atom in fat or other tissue types. An MRI machine, therefore, includes a strong magnet that creates a continuous magnetic field and RF coils for transmitting the excitation pulses and receiving the radio signals generated by the excited protons. Application of predictable variations or "gradients" in the magnetic field, using gradient coils within the magnetic bore, allows three-dimensional (3D) spatial localization of each signal. The raw data are initially mapped in "k-space" before a Fourier transformation to generate the final MRI image.

B. T1, T2, and image contrast. The rate of relaxation of an excited proton along the longitudinal axis (i.e., the direction of the external magnetic field) is described by its T1 time, whereas the transverse axis is described by its T2 time. T1 and T2 times depend on the molecular environment of the protons (intrinsic to the tissue characteristics) and the magnetic field strength. T1 and T2 relaxation times of different tissues are important determinants of image contrast and, although not measured directly, images can be either T1 or T2 "weighted" to facilitate tissue characterization.

C. Issues specific to CMRI. Cardiac and respiratory motion poses significant challenges to CMRI. In contrast to echocardiography, which is based on real-time imaging, CMRI sequences usually acquire a single image over several heart beats to optimize the spatial and temporal resolution. It is, therefore, necessary to gate images to the cardiac cycle with either an electrocardiographic or pulse signal. Electrocardiographic gating is usually retrospective, although prospective gating is sometimes useful, particularly in patients with arrhythmias. Respiratory motion is typically negated by performing breath-holds during the examination. In patients who are unable to maintain a breath-hold, averaging multiple MR signals may help to decrease the noise created by respiratory motion, at the expense of increasing the examination time by a factor of the *number of signals averaged*. Respiratory navigator sequences that coordinate imaging with a particular phase of diaphragmatic and hence respiratory motion are also effective, and they are typically used for pulse sequences that are too long for a single breath-hold, such as free-breathing whole-heart 3D coronary MRA sequences. Finally, real-time imaging using newer ultra-fast pulse sequences can be used in the absence of electrocardiographic or respiratory gating, at the expense of a significant decrease in temporal and spatial resolution.

D. CMRI pulse sequences and applications

1. **Spin echo.** Spin-echo sequences are characterized by a refocusing RF pulse after delivery of the initial excitation pulse. Rapidly flowing blood appears dark, hence they are also known as "black-blood" sequences. Spin-echo sequences provide still images, which are typically used for anatomic delineation of the heart and great vessels owing to their excellent tissue contrast and high signal-to-noise ratio (SNR). They are relatively insensitive to magnetic field inhomogeneities and artifacts related to ferromagnetic objects such as sternal wires and prosthetic heart valves. Turbo spin echo is a newer technique that provides faster acquisition times than standard spin echo does. The main disadvantage of spin-echo sequences is the relatively long time it takes to acquire an image, making them more susceptible to motion artifacts and unsuitable for cine imaging.
2. **Gradient echo.** Gradient echo sequences are characterized by the use of refocusing gradients after the delivery of the initial excitation pulse. Rapidly flowing blood appears bright, hence they are also known as "bright blood" sequences. Gradient echo is a fast imaging technique that is relatively insensitive to motion artifacts,

making it ideal for cine imaging. However, it has less tissue contrast and increased susceptibility to magnetic field inhomogeneities and ferromagnetic-related artifacts than spin-echo imaging but less than balanced steady-state free precession (B-SSFP). A variety of gradient echo sequences are widely used in CMRI for cine imaging, myocardial perfusion and scar assessment, coronary imaging, and MRA.

3. **Cine imaging.** The most widely used pulse sequence for cine imaging is a gradient echo sequence called balanced steady-state free precession (B-SSFP), which is characterized by high SNR, high image contrast between blood and myocardium, and low sensitivity to motion artifact. However, B-SSFP is relatively insensitive to blood flow and, therefore, can be suboptimal for imaging of valve dysfunction or intracardiac shunts, which can usually be better illustrated using other gradient echo pulse sequences, such as echo planar imaging or phase velocity mapping. In addition B-SSFP is also more susceptible to magnetic field inhomogeneities which can be problematic in patients with mechanical valves or other cardiac implants.
4. **Myocardial tagging.** RF pulses can be applied before the excitation pulse to generate dark saturation lines or grids on cine images, which are then tagged to the myocardium and further used to assess myocardial deformation. The tags can be used to help qualitatively assess myocardial motion and pericardial tethering or to quantitatively measure myocardial strain.
5. **Perfusion imaging.** Very fast gradient echo sequences are used for dynamic imaging of left ventricular (LV) myocardial perfusion during the first pass of a gadolinium contrast agent during rest and stress states. Fast gradient echo techniques are commonly used, such as fast low-angle shot or B-SSFP with a prepulse to null or darken the myocardium. Normally perfused myocardium shows an increase in signal intensity due to gadolinium contrast, whereas abnormally perfused areas remain dark or hypoperfused.
6. **Delayed imaging.** Delayed hyperenhancement imaging for myocardial scar or fibrosis is performed 10 to 30 minutes after injection of gadolinium contrast using gradient echo sequences with an inversion recovery prepulse to null signal from the myocardium. **Areas of myocardial scar or fibrosis have a larger extracellular space with a greater accumulation and slower washout of gadolinium and, therefore, appear bright compared with dark, normal myocardium on delayed imaging**.
7. **Phase-contrast velocity mapping.** The phase difference in the spin of protons in moving blood compared with nonmoving protons within a magnetic gradient is called the "spin phase shift" and is proportional to the velocity of the moving protons. A phase-encoded image is constructed, with the gray level of each pixel coded for velocity. Phase-contrast velocity mapping could be considered analogous to pulse wave Doppler echocardiography. It can be used to measure blood velocity and hence quantify cardiac output, shunts, and valve dysfunction. There are, however, limitations, given that the accuracy of this method is highly dependent on factors such as flow pattern, flow velocity, size, and tortuosity of the vessel. Flow-related signal loss can be a result of loss of phase coherence that can occur in cases of significant flow acceleration and even in higher orders of motion present in complex flow patterns.
8. **Magnetic resonance angiography.** MRA of the great vessels typically involves a 3D fast gradient–echo acquisition after injection of gadolinium contrast. The image resolution is typically $2 \times 2 \times 3$ mm, making MRA an excellent option for imaging of large to intermediate size arteries, but less optimal for imaging of smaller vessels.
9. **Parallel imaging.** A number of parallel imaging techniques make use of multiple receiving body coils to acquire extra data after each excitation pulse. This helps to decrease the imaging time and improve temporal resolution, but at the small relative cost of decrease in the SNR.

E. **Contrast agents.** A number of gadolinium chelates are used as contrast agents in clinical MRI. **Gadolinium significantly shortens the relaxation time of nearby**

protons, thereby increasing their signal intensity. These contrast agents are safe, with a low side-effect profile. Prevalence of adverse reactions is approximately 2% and includes transient headache, nausea, vomiting, local burning or cool sensation, and hives. Anaphylactoid reactions are extremely rare. Recently, gadolinium has been linked to a severe and rapidly progressive form of systemic sclerosis called **nephrogenic systemic fibrosis (NSF)**, which appears to be related to extracellular accumulation of gadolinium after its administration in patients with end-stage renal disease. The US Food and Drug Administration (FDA) has advised that **gadolinium contrast agents should not be administered to patients with a glomerular filtration rate of <15 mL/min. Caution should be exercised in patients with moderate or severe renal impairment**. Dialysis is only partly effective at filtering gadolinium and may not prevent development of NSF.

V. PRACTICAL CONSIDERATIONS

A. Safety

1. **Magnetic force.** Cardiac MRI scanners typically utilize powerful magnets of 1.5 to 3.0 T, several tens of thousands of times stronger than the earth's magnetic field (0.00005 T). Large or small ferromagnetic objects in the vicinity of the MRI magnet bore can become fast moving projectiles, which may cause severe injury to patients and/or damage the MRI scanner. A number of fatalities related to such events have been reported. Health-care professionals working in the vicinity of an MRI scanner require MRI safety training and should be vigilant to risk posed by patients and health-care professionals not familiar with the danger.
2. **Magnetic field gradients.** Switching of magnetic field gradients during a CMRI study produces high acoustic noise levels (up to 115 dB) and can also lead to peripheral nerve stimulation. The FDA has determined limits to the power of magnetic field gradients and noise exposure. Headphones and earplugs are recommended to prevent discomfort and hearing loss to patients and MRI staff in the vicinity of the scanner.
3. **Bioeffects of RF energy.** The majority of RF energy to the patient is dissipated as heat and is recorded as the specific absorption rate (SAR). One SAR equals 1 joule of RF energy per second per kilogram of body weight (i.e., watts per kilogram). The recommended SAR limit for the whole body is 4 W/kg.

B. Patient preparation

1. **Screening.** All patients should be screened for contraindications to MRI before the procedure (Table 51.2). Proper screening technique involves the use of a printed sheet and review of the completed form with the patient by an MR safety–trained health-care worker to verify the information.
2. **Patient size.** Although the maximum table load weight limit is fairly generous (~250 kg or 550 lbs), because of the fixed internal diameter of the magnet bore, very large patients may not fit within the MRI magnet. Typically, patients with a torso circumference of > 60 cm cannot be imaged. Discussion with the MRI technologist before scanning is recommended for specific recommendations related to your unit.
3. **Claustrophobia.** The enclosed space of the magnet poses problems for many patients, even those who do not have a history of claustrophobia. The study can usually be successfully completed with the help of clear communication with the patient before and during the procedure, presence of a friend or relative at the head of the MRI scanner, or light oral sedation (e.g., lorazepam 0.25 to 0.5 mg) 30 to 60 minutes before the procedure.

   Early versions of open MRI scanners had low magnetic field strength, gave poorer image quality than most closed systems, and required longer examination times. Newer open scanners include machines with higher magnetic field strengths and improved image quality and could become important alternatives in patients with claustrophobia.

4. **Attire.** Patients should wear a cotton hospital gown with no metal snaps. All metal items, jewelry, and nylon undergarments should be removed for reasons of safety and possible image degradation.
5. **Body coil.** Phased array body coils are placed on the patient's torso over the imaging area of interest. These use several smaller coils to acquire RF signals simultaneously and to facilitate parallel imaging. Some of these coils, for example, enable performance of 3D cardiac cine exams with full-ventricle coverage in a single breath-hold. The net result is not only better image quality but also reduced exam time for the patient.
6. **Electrocardiogram (ECG) monitoring.** A good electrocardiographic tracing is essential for CMRI. Although three or four MRI-safe, nonmetallic electrodes are placed on the patient's chest, and a single lead signal is used to trigger or gate the MRI images, the magnetic field affects the electrocardiographic tracing by inducing a voltage created by ions flowing within blood vessels (magnetohydrodynamic effect). This voltage artifact is commonly superimposed in the ST segment (during the ejection of blood in systole), which increases its amplitude causing false QRS detection in certain algorithms. Use of vector cardiogram allows the R-R interval to be registered as a 3D spatial vector that varies in magnitude and direction throughout the cardiac cycle. Furthermore, the use of fiber optic cables (instead of carbon leads) has also decreased the potential ECG interference of RF pulses and/or gradient field switches.
7. **Emergencies.** MRI is not appropriate in patients who are clinically unstable because of difficulties monitoring and treating patients within the magnet bore. Although MRI-safe equipment is available, it is safer to prescreen the patient's clinical status and determine the need of the MRI study before initiating the scanning.
8. **Pregnancy.** There is insufficient evidence regarding the safety of MRI in pregnant patients. Current guidelines state that MRI may be used in pregnant patients where other forms of nonionizing imaging are inadequate or if the examination provides important information that would otherwise require exposure to ionizing radiation.
9. **Children.** CMRI may be necessary in pediatric patients with congenital and acquired cardiovascular disease. Typically, children younger than 8 years will require general anesthesia.

VI. CLINICAL APPLICATIONS

A. Diseases of the aorta

1. **Aortic aneurysm.** MRI can clearly visualize both the aortic vessel wall and lumen. It is a reliable method for the identification, characterization, and follow-up of thoracic and abdominal aortic aneurysms, with accuracy comparable to that of CT. A combination of spin-echo sequences for characterization of the vessel wall, gradient echo cine sequences for dynamic imaging of the aorta and aortic valve, and contrast-enhanced magnetic resonance angiography (CE-MRA) for aortic and branch vessel luminography is characteristically used. The aorta may be highly tortuous and should be imaged in multiple planes, with double-oblique measurements performed from true short-axis cuts using reconstructed images.
2. **Aortic dissection.** MRI is a highly sensitive and specific technique for the detection of aortic dissection (sensitivity 98% to 100%, specificity 98% to 100%). Spin echo, B-SSFP, and CE-MRA are used to identify the intimal flap, true and false lumens, and involvement of aortic branch vessels, including the coronary arteries. Administration of contrast is not critical to the examination, so that MRI may be particularly helpful in patients in whom there is concern for significant renal impairment. In addition, potential complications of aortic dissection (e.g., pleural effusion, pericardial tamponade, and aortic regurgitation) are easily evaluated. However, the longer study acquisition time with MRI compared with CT and its unsuitability for imaging of unstable patients limit its application in

the acute setting. However, as a safe, noninvasive, relatively fast technique and without use of ionizing radiation, MRI is well suited for follow-up of both surgically and medically treated aortic dissections, in particular for young patients.

3. **Intramural hematoma and penetrating aortic ulcer.** Intramural hematoma can be considered as the *forme fruste* of aortic dissection with the spontaneous rupture of one of the vasa vasorum within the media of the aortic wall. It occurs in up to 30% of all acute aortic syndromes and appears as a smooth crescentic to circumferential area of thickened aortic wall without evidence of blood flow in the false channel on either B-SSFP or spin-echo sequences. Because of the short T1-relaxation time of fresh blood, differentiation from the adjacent mediastinal fat may be difficult. Intramural blood can be best detected on fat-saturated T1-weighted gradient echo or black-blood techniques. Furthermore, on spin-echo ("black-blood") imaging, the intramural hematoma may be isointense (acute) or hyperintense (subacute) relative to skeletal muscle. Penetrating aortic ulcers appear as deep ulcerations of an aortic atheroma that extend through the intima to disrupt the underlying media and cause bulging of the outer aortic contour. They commonly appear at the isthmus beyond the left subclavian artery and in the distal descending thoracic aorta near the diaphragm. If acute, there may be evidence of intramural bleeding in the rim adjacent to the ulcer.
4. **Atherosclerotic disease.** MRI can clearly show irregular thickening of the aorta in atherosclerotic disease. CE-MRA has good accuracy for detecting significant peripheral stenoses and occlusions. Recent research has focused on the ability of MRI to accurately identify and characterize atherosclerotic plaques in the aorta and carotid arteries, as well as the development of novel contrast agents that target atherosclerotic plaques.
5. **Trauma to the aorta.** MRI may detect chronic or missed aortic tears, usually related to a previous motor vehicle accident. Tears are usually found in the area of the ligamentum arteriosum and are characterized by a localized saccular aneurysm, with or without an associated periaortic hematoma.
6. **Aortitis.** In patients with inflammatory disorders affecting the aorta such as Takayasu's disease (which tends to also involve the arch branch vessels) or giant cell arteritis, MRI can accurately detect diffuse wall thickening of the thoracic and abdominal aorta (specially after gadolinium administration in T1-weighted images) as well as stenosis and occlusion of the aortic branch vessels (CE-MRA sequences). Special imaging sequences using T2-weighting and short-tau inversion recovery for fat suppression, one can also assess for (peri)vessel edema and wall thickening/inflammation, respectively.
7. **Aortic stents and stent grafts.** Aortic stents and stent grafts can be safely imaged using MRI; however, both cine sequences (gradient echo and B-SSFP) are prone to ferromagnetic artifacts. Spin-echo imaging can be used successfully to evaluate stent graft morphology. Artifacts may limit assessment for graft leaks using CE-MRA.

B. Assessment of ventricular function and coronary artery disease (CAD)

1. **Assessment of global ventricular function.** CMRI is now the gold standard for the assessment of ventricular mass, volumes, and systolic function. A significant advantage of CMR is its reproducibility and accuracy compared with 2D planar or projection techniques that depend on geometric assumptions in order to define mass and volume determinations. As a result, small changes in myocardial mass and/or volume can be detected over time or as a result of therapy. A typical approach is to perform a short-axis stack of B-SSFP cine sequences through the left and right ventricles. Manual or semi-automated tracing of the endocardial borders at end-diastole and end-systole is later performed off-line, and ventricular volumes and ejection fraction are calculated using Simpson's method of discs.
2. **Assessment of regional ventricular function.** As mentioned before, development of multichannel phase-array coils has enabled parallel imaging and significant

improvements in spatial and temporal resolution and scan times. This has led CMRI to become superior to echocardiography for precise assessment of regional wall motion. B-SSFP cine sequences provide excellent blood-myocardial contrast that permits clear definition of the endocardial border. Furthermore, myocardial tagging methods have also improved the assessment of regional myocardial function.

3. **Myocardial ischemia.** CMRI stress testing can detect myocardial ischemia with either wall motion or perfusion analysis. The use of dobutamine stress CMRI for wall motion analysis is more established than stress perfusion imaging with adenosine or dipyridamole. Studies of stress CMRI with dobutamine have revealed good sensitivity (83% to 92%) and specificity (86%) for the detection of significant CAD on a per-patient level. Furthermore, CMR tagging may further improve the accuracy of dobutamine CMR for ischemia detection. Stress perfusion imaging by CMRI appears to have slightly higher accuracy to that of thallium single-photon emission computed tomography (SPECT), with a sensitivity of 91% and specificity of 81% for the detection of significant CAD reported in a recent meta-analysis. The absence of ionizing radiation with MRI is an important consideration, particularly in younger patients. However, it is important to note that to accomplish these multicenter results, a facility capable of performing the stress testing with appropriate physician and staff training is required.
4. **Myocardial infarction (MI) and viability.** T2-weighted spin-echo sequences with fat suppression may show areas of increased signal intensity consistent with tissue edema in the acute or subacute phase of a MI. This field of myocardial edema has been gaining interest as a target for clinical trials in acute coronary syndrome. The concept is that the myocardium at risk would correspond to the edematous minus the scarred area (seen on delayed enhancement). However, this technique has potential imaging artifacts (cardiac/respiratory motion, low signal-to-noise ratio, slow flow, coil intensity profile, etc) which could hinder the reproducibility of results seen in single-center studies. The current state-of-the-art technique for myocardial scar detection remains delayed enhancement imaging with an inversion recovery gradient echo sequence 10 to 30 minutes after injection of a gadolinium contrast agent. This method shows areas of myocardial scarring as bright and normal myocardium as dark and has shown excellent correlation with the location and extent of scar on histopathologic analysis. The superior spatial resolution of CMRI makes it more sensitive for the detection of myocardial scar, and in particular subendocardial scar, than SPECT or positron emission tomography. In addition, detection of areas of microvascular obstruction, despite adequate epicardial vessel reperfusion, can also be identified with CMRI and appear to be associated with worsened outcomes. The transmural extent of scar is associated with myocardial viability. Transmural or near-transmural scar (> 50%) suggests nonviable myocardium, whereas the absence of myocardial scar suggests that functional recovery is very likely post revascularization.
5. **LV thrombus.** CMR is more sensitive than echocardiography for the detection of LV thrombus which is associated with a greater morbidity. Due to its high spatial resolution and tissue characterization capabilities, CMR can be quite advantageous in establishing or ruling out the diagnosis of intracardiac thrombus. The typical signal characteristics would include lack of contrast perfusion on 1st pass of Gadolinium and low-signal intensity on post-contrast delayed imaging with long inversion time (dark filling defect on the endocardial surface of the left ventricle).

C. **Nonischemic cardiomyopathies** There is increasing recognition of diffuse myocardial fibrosis occurring as a separate entity in a variety of conditions in the absence of ischemia, including hypertensive and diabetic heart disease, hypertrophic cardiomyopathy (HCM), and idiopathic dilated cardiomyopathy (DCM). In these situations, use of standard delayed enhancement CMR may become a problem: due to the often diffuse nature of the fibrotic process, no true normal, nonfibrotic myocardium can be used as a frame of reference.

To overcome this limitation, several new CMR techniques have been developed in trials for the detection of nonischemic myocardial fibrosis. Contrast-enhanced T_1 mapping using a modified Look-Locker inversion recovery sequence is the most promising technique that allows quantification of diffuse, nonischemic myocardial fibrosis with high temporal resolution within a single breath-hold. However, before it can be used for clinical applications, a more standardized histologically validated technique needs to be identified and assessed in clinical studies on various and larger groups of patients and in multicenter settings.

1. **Dilated cardiomyopathy.** CMRI is useful for precise assessment of cardiac morphology and function in patients with DCM. Delayed enhancement imaging typically shows focal or diffuse enhancement in a mid-myocardial distribution, with a predilection for involvement of the lateral LV wall. Delayed enhancement during the acute presentation of DCM has been shown to correlate with areas of active myocarditis. Thus, CMRI may help guide myocardial biopsy and improve its sensitivity. The extent of delayed enhancement tends to improve over time, but patchy areas often remain and may represent areas of ongoing inflammation or fibrosis.
2. **Hypertrophic cardiomyopathy.** MRI is accurate for the evaluation of the pattern and extent of hypertrophy, systolic anterior motion of the mitral valve, resting left ventricular outflow tract (LVOT) obstruction, and secondary mitral valve pathology and regurgitation. Because of the precise anatomic definition provided by CMRI, it is particularly helpful in planning for surgical myectomy or alcohol septal ablation. CMRI can also help identify abnormal chordal or papillary muscle attachments, which may contribute to LVOT obstruction and have been reported in up to 20% of patients with HCM. Delayed enhancement is frequently seen in patients with HCM and corresponds to areas of interstitial fibrosis. It is typically seen in areas of increased wall thickness as well as the right ventricular (RV) insertion points in the interventricular septum. The extent of delayed enhancement in patients with HCM is associated with the presence of risk factors for sudden cardiac death and associated with worse outcomes. However, further research is needed to prospectively validate and establish a role for myocardial fibrosis detection in risk prediction in patients with HCM.
3. **Restrictive cardiomyopathy (RCM).** Infiltration of the myocardium may lead to RCM, which is characterized by normal ventricular size and systolic function, severe diastolic dysfunction, and biatrial enlargement. LV and RV wall thickness may or may not be increased. CMRI can clearly visualize the typical findings of RCM and simultaneously distinguish it from constrictive pericarditis, the main differential diagnosis. In addition, specific causes of RCM may be diagnosed by CMRI. Amyloidosis is associated with thickening of the interatrial septum and atrial free walls, as well as increased LV and RV wall thickness. Furthermore, **delayed enhancement imaging can show a typical pattern of diffuse subendocardial enhancement in patients with cardiac amyloidosis**, albeit a particular characteristic, best seen in the contrast-enhanced T1-weighted scout (Look-Locker) sequence, is the "early" nulling of the infiltrated myocardium—almost concomitant with the blood pool. Several findings have been noted in patients with cardiac sarcoidosis, including areas of increased or decreased signal intensity on T2-weighted images and patchy areas of delayed hyperenhancement. **Hemochromatosis is characterized by extensive signal loss on T2-weighted images, resulting from iron deposition in the myocardium**. Measurement of the T2 relaxation time of the myocardium (T2* technique) allows more precise detection of iron overload. Furthermore, T2* technique is also prognostically important in patients with thalassemia major, identifying patients at high risk for heart failure and arrhythmia more so than serum ferritin and liver iron.
4. **Arrhythmogenic right ventricular dysplasia (ARVD). CMRI is the primary imaging test for patients with suspected ARVD**, although nonimaging criteria are also required to confirm the diagnosis. Although CMRI can identify typical features

of ARVD including RV wall thinning, fibrofatty replacement, and focal RV wall aneurysms, according to the recent revised Task Force criteria (Marcus et al, Circulation 2010) presence of RV dilation, global RV dysfunction, and/or regional hypokinesia are more important findings. Fibrofatty replacement of the RV myocardium on CMRI is no longer a diagnostic criterion requiring histopathology confirmation.

The CMRI examination for ARVD is different than that for other cardiomyopathies. Axial and short-axis stacks of high-resolution T1-weighted spin-echo images are acquired through the right ventricle for anatomic definition of the RV and LV myocardium. The spin-echo pulse sequences may be repeated with fat saturation prepulses to facilitate detection of fatty infiltration of the RV free wall. B-SSFP cines are performed in the same axial and short-axis imaging planes for identification of RV wall motion abnormalities. Finally, delayed enhancement imaging is performed for identification of myocardial fibrosis. ARVD must be differentiated from right ventricular outflow tract (RVOT) tachycardia, which is associated with less dramatic findings on CMRI, including focal wall thinning and regional hypokinesis above the level of the crista terminalis in the right ventricle and in the RVOT.

D. Diseases of the pericardium. Normal pericardium appears on MRI as a thin (≤2 mm) curvilinear line situated between the epicardial and pericardial fat. The normal pericardium is of low intensity on both T1- and T2-weighted imaging sequences.

1. **Pericardial effusions** are typically of low intensity on T1-weighted spin-echo images and of high intensity on gradient echo images. The exception is hemorrhagic effusion, which is of high intensity on T1-weighted spin-echo images and of low intensity on gradient echo images.
2. **Pericarditis and constriction.** MRI can readily define the presence and extent of pericardial thickening (≥ 4 mm), which may be present in acute pericarditis as well as constrictive pericarditis. In **inflammatory pericarditis**, the pericardium may have increased signal intensity on delayed enhancement imaging. CMRI is now the imaging technique of choice in the diagnosis and management of **constrictive pericarditis**. Typical features include **pericardial thickening and tethering associated with conical or tubular deformity of the ventricles**. Secondary changes include atrial enlargement, systemic and pulmonary vein dilation, hepatomegaly, ascites, and pleural effusions. Cine sequences can demonstrate features of constrictive physiology, including diastolic septal bounce and abrupt limitation of late diastolic filling of the ventricles, which is distinguishable from the more generally delayed diastolic filling patterns seen with restrictive cardiomyopathies. Furthermore, real-time cine sequences with free breathing are also important to demonstrate the interventricular dependence with exaggerated septal shift toward the left ventricle during inspiration. MRI is of limited value compared with CT in the evaluation of calcification of the pericardium because of its inability to reliably distinguish between fibrous tissue and calcification.
3. **Congenital absence of the pericardium**, which may be complete or partial and often left sided, can be demonstrated on CMRI and is typically associated with a leftward orientation and "teardrop" appearance of the heart. Insinuation of lung tissue between the aorta and pulmonary artery and between the inferior surface of the heart and left hemidiaphragm is also characteristically seen.
4. **Pericardial cysts.** These are benign developmental lesions formed when a portion of the pericardium is pinched off during embryogenesis. Pericardial cysts are classically seen at the right cardiophrenic angle. They typically contain fluid and are well marginated. Spin-echo images demonstrate round or ovoid lesions that are often contiguous with the normal pericardium. Simple cysts demonstrate low signal intensity on T1-weighted and high signal intensity on T2-weighted images. Hemorrhagic or proteinaceous filled cysts show high signal intensity on T1-weighted images.

E. Congenital heart disease. CMRI is now an essential tool in the management and follow-up of patients with congenital heart disease. Scans can be performed safely and

reliably from infancy through adulthood. CMRI provides excellent anatomic definition of simple and complex heart defects and precise, noninvasive quantification of cardiac function and shunts. Because of the complex morphology and physiology in a given patient, MRI examinations are tailored to the individual, with frequent adjustments made during the examination. Consequently, the supervising radiologist or cardiologist should have a thorough understanding of congenital heart disease and be ready to assist at the scanner during the test. Common applications of CMRI in adult congenital heart disease include noninvasive quantification of intracardiac shunts; evaluation of pulmonary regurgitation severity, ventricular volumes and function, and pulmonary artery branch vessel stenosis in patients post tetralogy of Fallot repair; identification of RVOT or branch pulmonary artery obstruction in patients who are post arterial switch for dextro transposition of the great arteries (D-TGA); evaluation of baffle stenosis or leak and RV dysfunction in patients post Mustard or Senning procedure for D-TGA; and assessment for dysfunction of the systemic ventricle in patients with congenitally corrected or levo transposition of the great arteries (L-TGA).

F. Valvular heart disease. Although echocardiography remains the primary imaging modality for the diagnosis and management of valvular heart disease, CMRI may provide additional important information in select cases. Particular strengths of CMRI in the evaluation of valve dysfunction include an often clearer visualization of valve morphology, valve planimetry, precise quantification of regurgitant volumes, accurate and reproducible measurement of ventricular volumes and function, and assessment of associated abnormalities (e.g., bicuspid aortic valve and ascending aortic dilation).

G. Cardiac masses. CMRI plays a major role in the evaluation of cardiac and paracardiac masses, because in addition to providing excellent anatomic detail, it also has the ability to perform tissue characterization. Thrombus is the most common intracardiac mass. Fresh thrombus has higher signal intensity than myocardium on T1-weighted images. Older thrombi may have increased signal intensity on T1-weighted and decreased signal intensity on T2-weighted images. Thrombi usually have low signal intensity on delayed enhancement imaging and do not demonstrate delayed enhancement even with long inversion time. Myxomas are the most common intracardiac tumor and in addition to a variegated and irregular appearance typically have higher signal intensity than myocardium on T2-weighted spin-echo imaging. Lipomas have a distinctive short T1 and, therefore, high signal intensity on T1-weighted images. Fat saturation sequences that null lipomatous tissue confirm the diagnosis. Fibromas are an uncommon cardiac tumor and are typically seen within the ventricular myocardium in pediatric or young adult patients. They have decreased signal intensity relative to myocardium on T2-weighted images and show rim enhancement on delayed hyperenhancement imaging.

Primary malignant tumors of the heart are rare. Imaging findings suggestive of a malignant cardiac tumor include a right atrial location, invasiveness without respect to the anatomical borders (ie: involvement of > 1 cardiac chamber, extension into the mediastinum or great vessels), associated hemorrhagic pericardial effusion and moderate or greater contrast perfusion/uptake and subsequent heterogenous delayed-enhancement of the cardiac mass. The most common is angiosarcoma followed by rhabdomyosarcoma. Angiosarcomas are most commonly seen in the right side of the heart and have a heterogenous appearance with hyperintense areas on T1-weighted images. Delayed hyperenhancement shows heterogenous enhancement, most marked in the periphery of the tumor. Metastatic disease of the heart is more common and typically involves the myocardium or pericardium. It is not always possible to differentiate benign from malignant cardiac tumors. Features of malignant tumors are local invasion, pericardial involvement, and increased signal intensity relative to myocardium after injection of gadolinium suggestive of increased vascularity. One limitation of CMRI is its reduced sensitivity for the detection of calcification in cardiac masses.

H. Pulmonary veins. With the growth of percutaneous RF ablation procedures for atrial fibrillation, imaging of the pulmonary veins is being increasingly performed.

CMRI with spin and gradient echo sequences complemented by CE-MRA is effective in assessing pulmonary vein anatomy and stenoses before and after the procedure.

VII. FUTURE APPLICATIONS

A. Coronary artery assessment. Coronary imaging with CMRI is usually performed with two-dimensional (2D) or 3D gradient echo sequences, with either fat saturation or T2 prepulses to enhance the signal difference between the coronary lumen and the surrounding myocardium, as well as decrease the venous signal. Three-dimensional acquisition with navigator-corrected (free-breathing) data set has higher signal-to-noise ratio when compared with 2D sequences and has now become the established approach to contrast-enhanced MR coronary angiography.

Although CMRI can be used reliably for the detection of coronary artery anomalies, it has not yet fulfilled its early promise for noninvasive imaging of coronary atherosclerotic disease, especially when applied to the broader patient population. The coronary arteries provide significant challenges to imaging by MRI because of cardiac and respiratory motion, their small size and tortuosity, normal cyclic variations in coronary flow, and competing signal from neighboring blood pools. Nevertheless, it can be valuable in patients with a low to intermediate pretest likelihood of CAD (< 20%) where the negative predictive value is similar to CT (> 95%), reliably ruling out CAD. These patients, who are often younger, predominantly female, and require more than one scan over their lifetime, would highly benefit from a radiation-free imaging study.

B. Molecular imaging. MRI shows significant promise for the selective imaging of target tissue or cells using novel molecular contrast agents. Magnetically labeled mesenchymal stem cells have been successfully tracked by MRI in a pig model of stem cell therapy for myocardial injury. Supermagnetic nanoparticles have also been used to detect atherosclerotic plaque in both animal and human studies. Similar to what has been seen in nuclear cardiology, this is a fast growing field with several lines of research.

C. Interventional CMRI. The use of MRI in interventional procedures is appealing because it does not entail exposure to ionizing radiation. MRI has been used successfully to guide a variety of interventional procedures including balloon angioplasty and interatrial septal puncture in animals. In addition, the first human MRI-guided stenting of the iliac arteries has been reported in a study of 13 patients.

Milind Desai

Cardiovascular Computed Tomography

I. INTRODUCTION. Cardiovascular computed tomography (CT) has continued to rapidly evolve over the past decade, gaining new and expanded indications for noninvasive assessment of the heart, great vessels, and peripheral vasculature. Technological improvements, including increasing numbers of detectors, improved temporal and spatial resolution, and advanced postprocessing, have broadened the clinical utility of this imaging modality. Advanced multidetector computed tomography (MDCT) scanners and new scanning protocols have significantly reduced radiation and contrast dosages. Numerous considerations are involved in the proper selection of cardiovascular CT protocols, and skilled operators are required to plan and interpret these examinations.

II. BASICS OF CARDIAC CT

A. CT physics. In CT, images are created by rotating an x-ray source emitting a fan-shaped beam of x-rays, which then pass through the body. Some x-rays are absorbed or scattered, but others are transmitted and subsequently sensed by detectors located directly across the x-ray source. In MDCT, the x-ray tube and detectors are mounted on a gantry that rotates rapidly around the patient as he or she passes through the scanner. As in traditional x-ray radiography, different structures **attenuate** the x-ray beam to differing extents depending on their atomic composition and density, as well as the energy of the incident photons. The data collected by the detectors then go through a complex set of mathematical reconstruction algorithms that create a set of axial images through the technique of **backprojection**. Each voxel in the resulting axial image is ascribed a specific attenuation value, which is expressed in **Hounsfield units (H.U.)**. Using a reference of 0 H.U. for water, –1000 H.U. for air, and +1000 H.U. for bony cortex, different points are assigned their respective attenuation values. This information is then converted into a grayscale image that can be manipulated by the interpreting physician.

B. Technical challenges for cardiac imaging

1. The fast cyclical motion of the heart requires high **temporal resolution** to avoid blurring or degradation of images due to cardiac motion artifact. In cardiac CT, image acquisition is referenced, or **gated**, to the cardiac cycle. Although data can be acquired throughout the cardiac cycle, most image data sets are reconstructed during periods of minimal cardiac motion, typically a brief 100- to 300-millisecond interval in late diastole (60% to 75% of the R-R interval).
2. High **spatial resolution** is required to image relatively small vessels such as the coronary arteries. Current MDCT scanners (64-slice) provide a spatial resolution of 0.4 mm compared with approximately 0.2 mm for invasive angiography, the gold standard.
3. Respiratory motion artifact can be minimized by having the patient hold his/her breath during image acquisition. Most clinically available scanners can cover the entire heart in 10 to 12 seconds, whereas the newest 256-slice MDCT scanners can cover this area in just one or two heartbeats.
4. Rapid improvements in CT technology and protocoling have outpaced research in the field. Many studies investigating the diagnostic and prognostic yield of information gained from cardiac CT are not based on the newest MDCT scanners—but rather on single-beam/detector systems. Further investigation involving randomized controlled studies has been limited by the ethical issue raised by radiation exposure, although this has also been significantly reduced by innovative scanning approaches.

C. Current CT hardware

1. **MDCT** involves using an x-ray tube mounted opposite multiple detector rows on a gantry, which is then rotated around the patient at a rapid rate (220 to 400 ms/rotation). The patient is moved at either a fixed or variable speed, or **pitch**, through the scanner. An increasing number of detectors allows for an increased *z*-axis (cranial–caudal) coverage, permitting faster scans with improved image quality due to less cardiac and respiratory motion artifact. Temporal resolution is improved by faster gantry rotation, the use of **two x-ray tubes** and detector arrays mounted at 90° angles to each other (dual-source MDCT), and special reconstruction techniques. Dual-source/dual-energy scanners provide substantial improvements by utilizing dual-source MDCT technology as well as dual-energy sources to improve temporal resolution and decrease scatter. The fastest scanners provide a temporal resolution of 83 to 105 milliseconds. Spatial resolution is largely determined by detector architecture (typically 0.4 mm isotropic resolution), although thicker slices (1 to 5 mm) can be acquired to reduce radiation dose according to the study indication. MDCT can be used for both

cardiac and noncardiac studies, and it is now the most widely used type of CT hardware for cardiac imaging.

2. **Electron beam computed tomography (EBCT)**, although rarely used today, was specifically developed for cardiac imaging. It involves the use of a rapidly oscillating electron beam reflected onto a stationary tungsten target. Because there is no mechanical motion within the gantry, EBCT is capable of very high temporal resolution (50 to 100 milliseconds). EBCT was used primarily for the quantitative detection of coronary artery calcification (CAC).

D. Image acquisition techniques

1. **Acquisition modes.** Most current MDCT scanners use spiral retrospectively gated acquisition techniques for cardiac imaging, as this mode provides the greatest flexibility in image selection during different phases of the cardiac cycle and the ability to edit the image data set for artifacts due to ectopic beats. Recently introduced software has made the older prospectively gated axial acquisition mode possible for cardiac imaging in selected patients, and this has resulted in a 60% to 70% reduction in radiation dose.
   a. **Sequential (axial, "step-and-shoot") mode.** Single transaxial slices are sequentially acquired while the patient table is incrementally advanced between successive rotations of the gantry.
   b. **Spiral (helical) mode.** Data are continuously acquired during constant rotation of the gantry with simultaneous, constant (*z*-axis) movement of the patient through the scanner. As the tube does not perform a complete rotation in any plane, x-ray data are interpolated from a series of sequential frames to create a single tomographic image.
2. **Electrocardiogram (ECG) gating**
   a. **Prospective triggering.** The trigger signal is derived from the patient's ECG based on a prospective estimation of the R-R interval. The scan is usually triggered to begin at a defined point after the R wave, usually allowing image acquisition to occur during diastole. Prospective ECG triggering is one of the most dose-efficient ways of cardiac scanning, as only the very minimum scan data needed for image reconstruction are acquired. Limitations of prospective triggering (or "**gating**") include the fact that the acquired data set will be of a limited portion (or phase) of the cardiac cycle only, limiting the opportunity for evaluating image data sets from other cardiac phases. In addition, prospective triggering depends greatly on the regularity of the patient's heart rate and can result in serious misregistration artifact in the setting of arrhythmia.
   b. **Retrospective gating.** Unlike prospective triggering, retrospective ECG gating collects data during the entire cardiac cycle. Once the scan is complete, data from specific periods of the cardiac cycle are used for image reconstruction by retrospective referencing to the ECG signal. This approach allows reconstructions to be made from multiple segments of the cardiac cycle and allows some assessment of cardiac function via four-dimensional reconstruction. However, retrospective gating requires higher radiation dose exposure, although this can be somewhat mitigated by **dose modulation** (see subsequent text).
3. **Other imaging considerations**
   a. **Segmented reconstruction** refers to image acquisition algorithms that use scan data from more than one cardiac cycle for image reconstruction. This can reduce the effective temporal resolution of the scan at the cost of a slight increase in radiation dose.
   b. **Dose (or tube current) modulation.** MDCT scanners may operate with fluctuating tube currents that increase radiation dose during portions of diastole (when diagnostic images are most likely to be obtained) and reduce it

during systole. Dose modulation typically reduces effective radiation dose by approximately 33%, and it is most effective at lower heart rates.

4. **Image reconstruction and interpretation.** Images are most frequently viewed from axial and double oblique planes, in which the three-dimensional data set is manipulated by the interpreting physician so that multiple planes can be viewed to assess cardiac morphology and coronary anatomy. Additional postprocessing techniques can be performed to provide further diagnostic information or, more frequently, to present to the referring physician.
   a. **Multiplanar reformation** involves creating straight or curved image planes by cutting orthogonally or obliquely through the three-dimensional acquisition. This aids in evaluating complex three-dimensional structures, such as the coronary arteries.
   b. **Maximal-intensity projections** are created by compressing a predetermined volume of image data into a two-dimensional projection of the brightest voxels. This is similar in principle to the two-dimensional images created by typical invasive angiography.
   c. **Three-dimensional or volume rendering** is an advanced image processing approach that uses semitransparent visualization of the outer contours of volumetric data, giving the appearance of a three-dimensional structure. Although often not as useful for assessing smaller structures, these reconstructions can be very helpful for understanding complex spatial relationships between major intrathoracic structures.
   d. **Four-dimensional or cine imaging** from spiral retrospectively gated images generates cine images of the CT data for evaluating cardiac and valvular function.

E. Contrast-enhanced imaging. Administration of iodinated contrast media increases the attenuation of the blood pool, improving vessel delineation and tissue characterization. When using contrast, image acquisition must be timed such that images are acquired when the blood pool saturation in the target structure is maximal. Various techniques exist to time the arrival of the contrast bolus in the arterial tree and initiate imaging. The specific risks of contrast media are discussed in Section **IV**.

III. INDICATIONS. The role of cardiac CT in evaluating patients with cardiovascular disease continues to evolve. Generally accepted indications for cardiac CT are listed in Table 52.1 and are discussed in the context of specific clinical situations in Section **VI**. The following is a brief listing of the more common indications for MDCT.

A. Evaluation of chest pain is performed in patients with low to intermediate pretest probability of disease and persistent chest pain after an equivocal stress test.

B. Suspicion of coronary artery anomalies. Due to high spatial resolution and the ability to create three-dimensional reconstructions of the vasculature, MDCT has very high sensitivity and specificity for coronary anomalies.

C. Pulmonary vein evaluation can be performed often before or after pulmonary vein isolation (PVI) for atrial fibrillation.

D. Evaluation of cardiac masses in conjunction with or when other modalities such as transthoracic echocardiography (TTE), transesophageal echocardiography (TEE), or magnetic resonance imaging (MRI) are unrevealing.

E. Evaluation of pericardial disease in conjunction with or when other modalities such as TTE, TEE, or MRI are unrevealing.

F. Assessment of anatomy in complex congenital heart disease.

G. Presurgical evaluation, particularly before redo open heart surgery. MDCT can aid in describing prior bypass graft location, identifying safe sites for surgical approach.

H. Assessing graft patency after prior bypass surgery is feasible in many cases, although it is sometimes limited by artifacts related to calcium and surgical clips.

TABLE 52.1 Appropriate Indications for Cardiac Computed Tomography

Category	Specific appropriate indications
Suspected CAD with symptoms	Intermediate pretest probability of CAD with uninterpretable ECG or unable to exercise
	Acute chest pain with intermediate pretest probability of CAD and no ECG changes and negative serial enzymes
	Evaluation of anomalous coronary artery anatomy
	Chest pain syndrome with uninterpretable or equivocal stress test (exercise, perfusion, or stress echo)
Evaluation of intra- and extra-cardiac structures	Evaluation of cardiac mass in patients with limited images from TTE, MRI, or TEE
Pericardial disease	Evaluation of pericardial conditions (pericardial mass, constrictive pericarditis, or complications of cardiac surgery) in patients with limited images from TTE, MRI, or TEE
Congenital heart disease	Assessment of complex congenital heart disease including anomalies of coronary circulation, great vessels, and cardiac chambers and valves
Pulmonary vein anatomy	Evaluation of pulmonary vein anatomy prior to invasive radiofrequency ablation for atrial fibrillation
Biventricular pacing	Noninvasive coronary vein mapping prior to placement of biventricular pacemaker
Aortic disease	Evaluation of suspected aortic dissection or thoracic aortic aneurysm
Pulmonary disease	Evaluation of suspected pulmonary embolism
Surgical planning	Noninvasive coronary arterial mapping, including internal mammary artery, prior to repeat cardiac surgical revascularization

CAD, coronary artery disease; ECG, electrocardiogram; MRI, magnetic resonance imaging; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

Adapted from the ACCF/ACR/SCCT/SCMR/ASNC/NASCI/SCAI/SIR 2006 appropriateness criteria for cardiac computed tomography and cardiac magnetic resonance imaging. *J Am Coll Cardiol.* 2006;48:1475–1497.

I. **Evaluation of aortic disease.** MDCT is the test of choice for evaluating aortic aneurysm and suspected aortic dissection. It can be useful in the long-term follow-up of patients who have undergone prior aortic surgery or endovascular stenting.

J. **Evaluation of suspected pulmonary embolism (PE).**

IV. CONTRAINDICATIONS. Unlike with cardiac MRI, few absolute contraindications exist for cardiac CT. However, there are important risks associated with radiation and/or contrast exposure that must be weighed against the benefits of the scan. **Relative contraindications** to CT scanning are listed below.

A. **Renal insufficiency.** Given the potential for contrast-induced nephropathy, patients with significant renal insufficiency (i.e., Cr > 1.6 mg/dL) should not undergo contrast-enhanced CT unless the information from the scan is critical and the risks/benefits are thoroughly discussed with the patient.

B. Contrast (iodine) allergy. Patients with allergic reactions to contrast should be pretreated with diphenhydramine and steroids before contrast administration. A prior anaphylactic response to contrast is generally felt to be an absolute contraindication to intravenous iodinated contrast administration in many institutions.

C. Recent intravenous iodinated contrast administration. Patients who have received an intravenous dose of iodinated contrast should avoid contrast-enhanced CT scanning for 24 hours to reduce the risk of contrast-induced nephropathy. For younger patients with normal renal function without risk factors for contrast-induced nephropathy, contrast doses of up to 150 to 200 mL per 24 hours are generally well tolerated.

D. Hyperthyroidism. Iodinated contrast is contraindicated in the setting of uncontrolled hyperthyroidism due to possible precipitation of thyrotoxicosis.

E. Atrial fibrillation, or any irregular heart rhythm, is a contraindication to coronary CT angiography due to image degradation from suboptimal ECG gating.

F. Inability to breath-hold for at least 10 seconds. Image quality will be significantly reduced due to respiratory motion artifact, if the patient cannot comply with breath-hold instructions.

V. SAFETY

A. Radiation exposure is recognized as an important risk of various cardiac imaging modalities, including CT. Radiation doses of cardiac CT scans vary greatly depending on the scan parameter settings, scan range (cranial–caudal length of the scan), gender (women receive more radiation due to breast tissue), and patient's body habitus (obesity increases exposure).

1. **Estimates of radiation dose from MDCT** have varied widely in the literature. **Effective dose** is an estimate of the dose to patients during an ionizing radiation procedure and is expressed in **millisieverts (mSv)**. For reference, the estimated dose from a chest x-ray is 0.04 to 0.10 mSv, and the average annual background radiation in the United States is 3 to 3.6 mSv. Invasive diagnostic coronary angiography provides effective doses of 2.1 to 4 mSv. In comparison, coronary CT angiography studies have reported doses ranging from 3.6 mSv to as high as 18 mSv, depending on the scan parameters, with most estimates ranging from roughly 4 to 11 mSv. Table 52.2 lists radiation dose ranges for the most commonly used cardiac imaging modalities.
2. **Feasibility of low-dose coronary CT angiography.** With the use of prospective ECG triggering, axial imaging modes, dose reduction, and software adaptations, recent studies have reported the feasibility of coronary CT angiography with comparable image quality and substantially reduced radiation doses (i.e., 1.1 to 3.0 mSv). This remains an area of active investigation.

B. Contrast-Induced Nephropathy. Iodinated contrast media can cause renal ischemia by reducing renal blood flow or increasing oxygen demand and may also have a direct toxic effect on tubular epithelial cells. If a contrast-enhanced CT study is necessary in patients with significant renal insufficiency, prophylactic measures should be taken to reduce the risk of renal damage. Most cardiac CT studies require between 80 and 100 cc of contrast dye.

1. **Risk factors**
   - **(a)** Preexisting renal insufficiency
   - **(b)** Diabetes mellitus
   - **(c)** Volume of contrast media
2. **Prophylactic measures** include saline hydration, use of low-osmolar agents, and sodium bicarbonate infusion, although the data for each of these measures remain somewhat controversial. The use of *N*-acetylcysteine has been shown to have no effect in slowing the progression of contrast-induced nephropathy.

TABLE 52.2 Estimated Radiation Exposure from Cardiac Imaging Procedures

Diagnostic procedure	Typical effective dose (mSv)	Equivalent period of natural background radiation
Natural background radiation	3–4 (range 1.5–7.5)	1 y
Chest x-ray (PA and lateral)	0.04	6 d
Transatlantic flight	0.03	5 d
Lung ventilation (Kr 81m)	0.1	2–4 wk
Lung perfusion study (Tc 99m)	1	4–6 mo
Calcium scoring	0.8–2	3–6 mo
CT head	2	8 mo
Cardiac catheterization (diagnostic)	3–4	1 y
64-Slice MDCT (with dose modulation)	8–12	2–3 y
Myocardial perfusion (Tl 201)	15–18	4–5 y
CT abdomen/pelvis	10–20	3–6 y
Cardiac PET	14–20	4–6 y

PA, posterolateral; MDCT, multi-detector computed tomography; mSv, millisievert; CT, computed tomography; PET, positron emission tomography; R, Roentgen units.

VI. CLINICAL APPLICATIONS

A. Coronary calcium scoring uses the observation that coronary calcium is a surrogate marker for coronary atherosclerotic plaque. Studies have shown that the complete absence of coronary artery calcium makes the presence of significant coronary luminal obstruction highly unlikely and indicates a very low risk of future coronary events. Men tend to have higher calcium scores, and individuals of either gender with renal insufficiency or diabetes tend to have higher coronary calcium scores.

1. Either noncontrast EBCT or MDCT can be used (typically with 3.0 mm slice thickness). Contrast is not necessary because calcium is readily identified secondary to its very high x-ray attenuation coefficient (high H.U. score).
2. The **Agatston CAC volume score** is the most frequently used scoring system. It is derived by measuring the area of each calcified coronary lesion and multiplying it by a coefficient of 1 to 4, depending on the maximum CT attenuation within that lesion. It is important to realize the reproducibility of the Agatston score before applying the recommended guidelines for cut-off points. Importantly, the variability in the score has very little meaning at the very high and very low scores. Inter-reader variability can be as high as 3%.
   a. The **CAC score** can be classified into five groups: (1) zero, no coronary calcification; (2) 100, mild coronary calcification; (3) > 100 to 399, moderate calcification; (4) > 400 to 999, severe calcification; and (5) > 1000, extensive calcification.
   b. The CAC score is age specific and gender specific. Therefore, there has to be a comparison of the individual data with a "normal" cohort in order to produce meaningful data, usually presented as the percentile distribution. In

general, CAC develops 10 to 15 years later in life in women than in men. Similarly, CAC is generally five to seven times lower at any given age in women than in men.

c. In a typical cohort of coronary artery disease (CAD) patients, the median CAC score is 975 for men and 370 for women. In comparison with a CAC score of 0, the presence of any CAC is associated with a fourfold risk of coronary events over 3 to 5 years.

d. In patients at intermediate clinical risk for coronary events (e.g., by Framingham score), the CAC score can help reclassify patients to a higher or lower risk group. For instance, a CAC score of 0 confirms low risk of events. Conversely, a CAC score of > 400 is observed with a significant cardiac event rate (> 2% per year) in patients who appear to be of intermediate risk per Framingham score.

e. Because statins have no documented effect on CAC progression, there is no value in repeating CAC in persons with a score of > 100 or the 75th percentile.

3. However, not every atherosclerotic plaque is calcified, and even the detection of a large amount of calcium does not imply the presence of significant stenoses. Therefore, it adds only incrementally to traditional risk assessment and should not be used in isolation. The test is most useful in intermediate-risk populations, in which a high or low score may reclassify individuals to a higher or lower risk group, respectively. Unselected screening is not recommended.

B. Coronary CT angiography has been shown to be an accurate noninvasive modality for visualizing the coronary arteries, with high sensitivity (85% to 95%) and specificity (95% to 98%) compared with invasive angiography as the gold standard.

1. Coronary CT angiography for evaluating CAD is most useful in low- to intermediate-risk patients with angina or anginal equivalent. The **negative predictive value** of coronary CT angiography is uniformly high in studies, approaching 95% to 100%; in other words, coronary CT angiography is an excellent modality for ruling out coronary disease.
2. Patients who are generally poor candidates for coronary CT angiography include those who are likely to have heavily calcified coronary arteries (older than 75 years, end-stage renal disease, and Paget's disease), atrial fibrillation/flutter, frequent ventricular ectopic beats, or uncontrolled tachycardia. Quantification of stenosis severity is often impossible in densely calcified arteries, whereas image quality is significantly degraded in patients with arrhythmias or tachycardia. The negative predictive value dropped to 83% in one study, where patients with Agatston's CAC score of < 600 were included.
3. Known severe CAD is generally a contraindication to coronary CT angiography. However, cardiac CT has been shown to have high sensitivity and specificity for the assessment of bypass graft patency in patients with previous coronary artery bypass grafting (see subsequent text).
4. **Stent patency**. Patients with prior coronary artery stents are generally poor candidates for CAC and CT angiography, although selected patients with proximal left anterior descending or left main stents may be successfully imaged. Current CT technology does not allow for the accurate quantification of in-stent stenosis severity, due to blooming artifact from the metallic body of the stent.
5. When assessing the coronaries, **noncalcified plaque** appears as a low to intermediate attenuation irregularity in the vessel wall. **Calcified plaques** are bright, high-attenuation lesions in the vessel wall and may be associated with positive remodeling of the vessel. Densely calcified plaques are often associated with **calcium blooming artifact**, which can lead to overestimation of luminal stenosis severity.

6. The accuracy of coronary CT angiography is highest in the larger proximal to medium vessels, which are more likely to benefit from an invasive management strategy. Coronary stenoses are generally categorized as mild (< 50% diameter stenosis), moderate (50% to 70% diameter stenosis), or severe (> 70% diameter stenosis).

C. Bypass graft imaging

1. **Graft location.** MDCT can accurately characterize the origin, course, and touchdown of prior bypass grafts using intermediate slice thickness (e.g., 1.5 mm). This can be important for surgical planning (see details in subsequent text of this chapter).
2. **Graft patency.** Using a protocol similar to that used for coronary artery assessment (> 1 mm slice thickness), patency of both arterial and venous bypass grafts can be assessed. Studies have suggested that the sensitivity and specificity of MDCT for detecting stenosis or occlusion of bypass grafts, when compared with invasive angiography, are 97% and 97%, respectively. Occasionally, artifacts related to metallic clips can interfere with assessment of the distal anastomosis of an arterial graft (internal mammary or radial artery graft).

D. Coronary artery anomalies. Due to the three-dimensional data acquisition, MDCT is an excellent modality for assessing patients with known or suspected coronary artery anomalies. MDCT can accurately assess the origin and course of anomalous coronaries and can describe the relationship of the coronary artery to neighboring structures. Although MRI can also be used to assess anomalous coronaries without the need for radiation exposure, the spatial resolution, ease of data acquisition, and reliable image quality of MDCT make it a reasonable first choice. Intramyocardial **bridging** can also be detected with high sensitivity, although the clinical significance of this relatively common finding is uncertain.

E. Cardiac morphology/function. Contrast-enhanced MDCT can provide high-resolution morphologic images of the cardiac chambers as well as accurate assessment of right and left ventricular systolic function. However, other imaging modalities such as echocardiography or MRI, which do not require radiation exposure, are generally preferred initially for assessing cardiac morphology.

1. Patients with prior **myocardial infarction** can have fibrous replacement of myocardium with or without calcification, ventricular wall thinning, aneurysm formation, and cavitary thrombus. This is a rare indication for cardiac CT; rather, it is studied with delayed enhancement MRI.
2. **Ventricular dysplasia** is characterized by fibrous and/or fatty replacement of myocardium, ventricular wall thinning and/or focal aneurysm formation, and ventricular cavity dilation with regional or global wall motion abnormalities.
3. **Mass.** CT provides somewhat less information about tissue type than cardiac MRI, although the attenuation of a mass (in H.U.) can be helpful. For instance, lipomas have low CT numbers, cysts have water density (i.e., 0 to 10 H.U.), and thrombi have low to intermediate CT numbers. Atrial myxoma can be visualized easily in the left atrium, although right atrial masses may be difficult to visualize due to contrast mixing at the junction of the right atrium and inferior vena cava (IVC).

F. Pericardial diseases. The pericardium appears as a thin line (1 to 2 mm) surrounding the heart, usually visible with a small amount of adjacent pericardial fat. The pericardium normally enhances with contrast administration; hyperenhancement of the pericardium in the appropriate clinical setting is characteristic of pericarditis.

1. By CT, **congenital absence of the pericardium** is easily diagnosed.
2. Findings of pericardial **constriction** on CT include irregular pericardial thickening and calcification, conical or tubular compression of one or both ventricles,

enlargement of one or both atria, dilation of the IVC, and a characteristic diastolic bounce of the interventricular septum.

3. Pericardial effusions can be reliably detected by CT, and a small amount of fluid is normal even in healthy subjects. Pericardial tamponade is better evaluated by echocardiography, however, due to its ability to provide hemodynamic information.
4. A pericardial **cyst** will appear as a well-circumscribed paracardiac mass with characteristic water attenuation (H.U. = 0), usually in the right costophrenic angle.
5. Both primary **neoplasms** and, more commonly, metastatic neoplasms can be visualized in the pericardium.

G. Congenital heart disease. MDCT may be used in selected patients in whom echocardiography is nondiagnostic or inadequate and MRI is not available. The ability to evaluate cardiovascular anatomy in multiple planes is often helpful for delineating cardiac morphology in congenital heart disease, particularly with regard to the relationship of the great vessels, pulmonary veins, and coronary arteries. Specific situations in which MDCT is helpful include "hard-to-find" adult shunt detection (sinus venosus atrial septal defect and patent ductus arteriosus); visualization of pulmonary arteries in cyanotic congenital heart disease; precise definition of aortic anatomy in Marfan's syndrome or coarctation; and definition of partial or total anomalous pulmonary venous drainage. Additionally, CT can be useful for follow-up imaging in patients with congenital heart disease who have had prior pacemaker or ICD implantation, such as L-transposition of the great arteries.

H. Diseases of the aorta constitute a common and important indication for CT examinations. Contrast-enhanced MDCT is nearly 100% sensitive and specific for evaluating acute aortic syndromes. ECG gating is critically important for studies of the aortic root and ascending aorta, given the propensity for motion artifacts to appear similar to dissection flaps on nongated studies.

1. **Acute aortic dissection** (see Chapter 26) is characterized on CT by visualization of a dissection flap (i.e., separation of the intima from the media) that forms true and false lumens. The CT study can characterize the origin and extent of the dissection, classify it as type A or B, assess for concomitant aneurysmal aortic dilation, and identify branch vessel involvement.
2. **Aortic intramural hematomas** are believed to be caused by spontaneous hemorrhage of the vaso vasorum of the medial layer. They appear as crescent-shaped areas of increased attenuation with eccentric aortic wall thickening. Unlike dissections, hematomas do not spiral around the aorta.
3. **Aortic aneurysm** is a permanent dilation of 150% of the normal aortic caliber (usually > 5 cm in the thoracic aorta and > 3 cm in the abdominal aorta). Given the often tortuous course of a dilated aorta, it is important that these measurements be made in the true short axis of the aorta, as oblique cuts can result in erroneous overestimation of the aortic diameter. Quantitative measurements of an aortic aneurysm can be made for planning endovascular repair with a **stent graft**.
4. **Penetrating atherosclerotic ulcer.** These tend to be focal lesions of the descending thoracic aorta that appear as contrast-filled irregular outpouchings of the aortic wall.

I. Evaluation of pulmonary veins. In the context of electrophysiology interventions such as PVI, preprocedural MDCT can be used to define pulmonary venous anatomy and identify supernumerary veins, and postprocedural MDCT can be used to evaluate for pulmonary vein stenosis. Additionally, in the setting of congenital heart disease, CT can be used to identify anomalous pulmonary venous return.

J. Evaluation of PE. MDCT is highly accurate in detecting PE, which appears as a filling defect in the pulmonary arteries. This modality is most sensitive for proximal (main through segmental branches) thrombi, and small, distal emboli may be missed.

K. Valvular heart disease. Visualization of the valve leaflets, particularly the aortic valve, is feasible with newer generation scanners due to their improved temporal resolution. Nonenhanced MDCT is also useful for assessing mechanical valve leaflet motion in cases of suspected thrombosis or infection.

L. Surgical planning. The utility of MDCT in surgical planning before cardiothoracic surgery, particularly for reoperations, is increasingly recognized. Preoperative scans can evaluate the proximity of mediastinal structures to the sternum (i.e., aorta, right ventricle, and bypass grafts) and the degree of aortic calcification (i.e., to guide cannulation sites) and concomitantly provide information about cardiac morphology (e.g., presence of a ventricular aneurysm).

M. Peripheral arteries. MDCT can also be used to evaluate peripheral arteries, including the carotid, renal, visceral, and lower extremity vessels. Indeed, imaging these vessels is generally more straightforward than coronary imaging, due to their large caliber and minimal motion. CT can be used for planning and follow-up of vascular disease in these peripheral vascular beds. Given the larger caliber of these vessels, assessment of stent patency is often quite feasible.

Electrophysiologic Studies

I. INTRODUCTION. Electrophysiologic studies (EPSs) are a specialized form of cardiac catheterization that help identify, characterize, and manage cardiac arrhythmias. Over the past 25 to 30 years, EPSs have advanced our knowledge of mechanisms of cardiac arrhythmias and revolutionized the way these arrhythmias are managed. The studies should be performed by trained clinicians with the help of skilled laboratory personnel in appropriately equipped laboratories. A joint task force of the American College of Cardiology and the American Heart Association in collaboration with Heart Rhythm Society has published guidelines outlining the accepted indications and the training required for personnel performing EPSs.

II. INDICATIONS. The indications for EPSs can be divided into three broad categories: bradyarrhythmias, tachyarrhythmias, and syncope.

A. Bradyarrhythmias can be caused by sinus node dysfunction, atrioventricular (AV) nodal disease, or infranodal conduction system disease. EPSs for bradyarrhythmias are rarely necessary because the decision to implant a pacemaker depends primarily on correlation between symptoms and documented bradycardia or demonstration of severe bradycardia or prolonged pauses. EPSs should complement the clinical evaluation, conventional 12-lead electrocardiogram (ECG), and Holter or event monitor. EPSs can be of value in identifying disorders associated with adverse outcome, such as severe infranodal conduction system disease.

B. More often, EPSs may suggest bradycardia as the underlying disorder among patients with **syncope** of unknown cause. Thus, patients with syncope of uncertain cause may benefit from EPSs.

C. EPSs are of tremendous value in evaluating **tachyarrhythmias**. They are generally more successful in reproducing re-entrant cardiac rhythms than those caused by triggered activity or enhanced automaticity. Among patients with re-entrant tachyarrhythmias, EPSs are useful in documenting the presence of the anatomic or physiologic substrate responsible for the arrhythmia, defining electrical mechanism of the arrhythmia and its associated hemodynamic response, as well as guiding therapy. The response of the tachyarrhythmia during an EPS to various drugs or pacing maneuvers may also be helpful in further defining the underlying substrate and prognosis.

III. EQUIPMENT AND SETTING

A. The most important element in the performance of a safe and useful EPS is the presence of **well-trained personnel**. The presence of at least one trained physician and well-trained laboratory support personnel, including a nurse, as well as engineering assistance to maintain and repair the laboratory equipment is necessary. Personnel involved should be familiar with basic electrophysiologic and electropharmacologic principles, the indications for EPSs, and the various diagnostic and therapeutic modalities that can be used in the laboratory.

B. It is important that the laboratory be equipped with appropriate high-quality **radiographic equipment**.

C. Appropriate selection of **tools** is a very important aspect of the performance of a safe and cost-effective EPS. The minimum instrumentation required for a complete study is a stimulator, an amplifier, display monitors, reliable recording devices, and an external defibrillator.

1. The **stimulator** must be capable of burst pacing, delivery of at least three or four extra stimuli, synchronization to appropriate electric events during intrinsic or paced rhythms, and an adjustable current output. An appropriate unit should have a constant current source and minimal current leakage. It should also be relatively easy to manipulate.
2. The **junction box** connects the electrode catheters to the recording apparatus and the stimulator.
3. **Recording** is best achieved on solid media (e.g., CD or other optical media).
4. The presence of at least two functioning **external defibrillators** is extremely important, particularly during studies in which ventricular arrhythmias may be induced.
5. The presence of a cardiac surgical team in the same institution is not mandatory for routine EPS or simple radiofrequency (RF) ablation procedures. However, for more complex RF ablation procedures where full heparinization is used and where cardiac perforation is a potential complication, the presence of a cardiac surgical team allows for prompt, definitive therapy when surgical intervention is required.

D. **Intracardiac signals** are recorded using various **electrode catheters**.

1. The most common catheters used are **quadripolar woven Dacron polyester** or **polyurethane**. The distal poles of these catheters can be used for pacing.
2. For general purpose sensing and pacing in the atrium or ventricle, a **nondeflectable catheter** is usually sufficient. Deflectable catheters facilitate mapping and ablation by allowing more precise movement.
3. Interelectrode distance varies from 2 to 10 mm. Smaller interelectrode distance is useful for precise mapping and timing.
4. For most EPSs, **bipolar recording** is used. However, in some situations, especially during mapping of tachyarrhythmias, unipolar recording can be of value in localizing the earliest sites of activity.

IV. TECHNIQUES AND PROCEDURES

A. Preprocedure preparation

1. Before the patient is taken to the EPS laboratory, a **discussion** of the indications and proposed procedure is conducted with the patient, and informed consent is obtained.
2. For most indications, EPS is an **elective** procedure. The patient's condition should be clinically **stable** at the time of the study. EPSs on patients who are unstable, including those with active, recent, or untreated coronary disease or those with clinical heart failure, carry much higher risk for complications.
3. **Electrolytes, serum digoxin level, and bleeding measurements** are checked and verified as being within the acceptable range.
4. Conscious sedation using a mild **sedative** (e.g., a benzodiazepine) and analgesic is administered.
5. The patient is attached to continuous ECG and blood pressure **monitoring** devices.

B. Access and catheter placement

1. The usual approach to inserting electrode catheters is through the **femoral veins under local anesthesia**, unless there is a clear contraindication to this approach, such as the presence of deep venous thrombosis or an inferior vena cava filter. In

the latter situations or when a coronary sinus (CS) catheter is difficult to insert, a superior vein approach may be used. We routinely utilize vascular ultrasound to directly visualize the femoral venipuncture, particularly when patients are on anticoagulation. This real-time visualization clarifies anatomic variants and enables us to avoid inadvertent arterial needlesticks and multiple passes that can lead to bleeding complications. Sheaths are then introduced into the vein over guidewires via the modified Seldinger technique.

2. Up to three **introducers** are placed in each femoral vein depending on the planned procedure. For patients with **left-sided bypass tracks or left ventricular (LV) tachycardia**, access to the left side of the heart is necessary. This can be achieved through the retrograde transaortic approach via an arterial access or by transseptal puncture via a femoral vein access. Systemic heparin is used for all left-sided procedures, and activated clotting time is monitored during the procedure to achieve adequate levels of anticoagulation.
3. **For a complete EPS, three catheters are needed.**
   a. One catheter is placed in the **high right atrium,** preferably in the appendage or against the high lateral wall. Another is placed in the **right ventricular (RV) apex**, and the third is placed across the **tricuspid valve** to obtain a His electrogram.
   b. To obtain a **His electrogram**, the electrode catheter is advanced into the right ventricle across the anterior septal portion of the tricuspid valve. Under gentle clockwise torque, the catheter is then slowly withdrawn to straddle the tricuspid valve. A high-frequency sharp deflection that precedes ventricular activation and follows septal atrial activation represents a **His** or **proximal right bundle potential**. If the catheter is drawn further, this sharp signal occurs slightly earlier. A satisfactory position of the His catheter is achieved when an atrial signal is recorded followed by the His potential and, finally, the ventricular potential is recorded via the same pair of electrodes.
4. In **supraventricular tachycardia (SVT)** studies, when a left-sided accessory pathway or left atrial origin is suspected, an octapolar or decapolar catheter may be placed in the CS rather than in the high right atrium. This more stable catheter position allows mapping of the left AV groove along the mitral annulus. Although the CS is easily entered from the superior venous approach, successful catheterization is expected in most attempts through the femoral approach as well. The catheter is placed in the CS with the proximal electrodes just inside the CS ostium.

C. Baseline assessment

1. When all the catheters are in place, a baseline ECG (generally leads I, aVF, V_1, and V_6) and intracardiac electrograms are obtained (Fig. 53.1).
2. In general, **cycle lengths** rather than beats per minute are measured. The following measurements are made at baseline: sinus cycle length and PR, QRS, QT, AH, and HV intervals. To convert an arrhythmia's rate from cycle length to beats per minute, divide 60,000 by the cycle length to obtain the arrhythmia rate in beats per minute.
   a. The **AH interval** is measured from the onset of the local A deflection to the H deflection on the His electrogram.
   b. The **HV interval** is measured from the H deflection on the His electrogram to the earliest ventricular activity in any lead (surface or intracardiac).
3. When measurements are made during pacing, it is important to **measure from the resulting deflection** rather than from the pacing artifact to avoid errors caused by latency (delay between the pacing artifact and activation at the recording site).
4. All measurements are recorded in **milliseconds**. Interpretation of baseline intervals is shown in Figure 53.2.

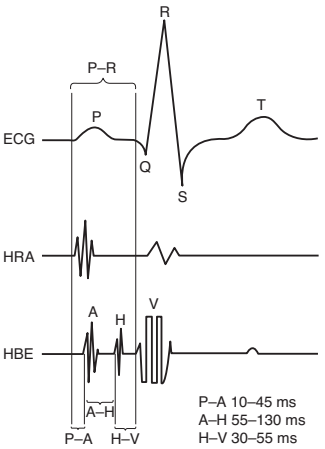

FIGURE 53.1 Normal baseline intervals. Typically, up to four surface ECGs (I, aVF, V_1, and V_6) are displayed along with atrial (CS), His (HBE), and ventricular (RVA) electrograms. CS7–8 refers to the proximal bipolar CS electrogram. Fast sweep speeds are used, ranging from 100 to 400 mm/s. On the time scale, each large division is 100 milliseconds, and each minor division is 10 milliseconds. In addition to intervals, pattern of atrial and ventricular activation should be evaluated. If the CS catheter is placed correctly (see text), the earliest A in sinus rhythm is seen on the HRA electrogram (not shown), then on the His electrogram, and progressively later along the CS electrograms. In the absence of bundle branch block or left-sided accessory pathway, the earliest ventricular activity is seen on right-sided electrograms (His and RV electrograms). (Adapted from *Dorland's Illustrated Medical Dictionary.*) CS, coronary sinus; ECG, electrocardiogram; HBE, His bundle electrogram; HRA, high right atrium; RVA, right ventricular apex.

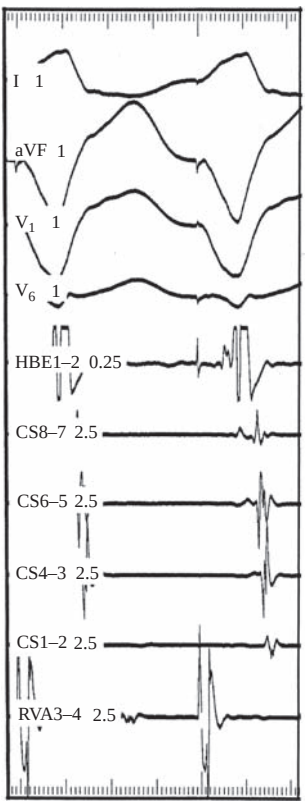

FIGURE 53.2 Programmed ventricular stimulation using double extra stimuli in a patient with AV node re-entry tachycardia. Note that the earliest retrograde atrial activity is seen on the His electrogram. AV, atrioventricular; CS, coronary sinus; HBE, His bundle electrogram; RVA, right ventricular apex.

D. Programmed stimulation

1. After baseline measurements are made, programmed stimulation is performed. The protocol used depends on the indication for the study and varies among institutions. During programmed stimulation, the **hemodynamic response** of the patient to pacing and induced tachycardia is closely monitored. For example, rapid ventricular pacing in patients with structural heart disease may result in transient hypotension. If this occurs, pacing should be limited in duration and adequate time between pacing drive trains should be allowed for hemodynamic recovery.
2. **Pacing stimuli** are usually delivered at 1 or 2 millisecond pulse width and at twice diastolic pacing thresholds. This is important during ventricular stimulation because pacing at higher outputs increases the risk of inducing nonclinical rhythms. There are two main types of programmed stimulation: burst pacing and the extra stimulus technique.
   a. **Burst pacing** involves continuous pacing at rates faster than the patient's intrinsic rate.
   b. In the **extra stimulus technique**, premature beats are introduced either during intrinsic rhythm (sensed extra stimuli) or after a paced drive train (paced extra stimuli). Extra stimulus techniques are useful in evaluating refractory periods of the AV node, atrial tissue, ventricular tissue, and accessory pathways. It is possible to evaluate infranodal conduction system refractory periods with atrial or ventricular stimulation. Extra stimulus techniques are also useful in inducing, terminating, and identifying re-entrant arrhythmias.
      (1) In the **sensed extra stimulus** technique, a single extra stimulus (S_2) is introduced initially with a coupling just below the intrinsic rate. The coupling interval is reduced progressively by 10 to 20 milliseconds until the premature stimulus no longer captures. A pause of 2 to 5 seconds is allowed between stimulation sequences. Multiple extra stimuli (S_3, S_4) can be added if necessary and the sequence repeated.
      (2) In the **paced extra stimulus** technique, a drive train of 6 to 10 beats at a fixed cycle length is followed by the premature beat. The drive train cycle length (S_1S_1) usually ranges from 350 to 800 milliseconds (most frequently 400 to 600 milliseconds) but depends on the resting heart rate. When this technique is used, testing at two drive train cycle lengths is recommended. The premature stimulus (S_2) is introduced with a coupling interval just below the S_1S_1. The coupling interval of the premature stimulus is decreased progressively by 10 to 20 milliseconds until it no longer captures. The longest coupling interval (S_1S_2) that does not capture the myocardium is the absolute refractory period. S_3 and S_4 are added if necessary. This protocol can be varied depending on the indication and operator preference.
3. **Continuous monitoring** and recording of external and intracardiac electrograms is maintained throughout programmed stimulation. When a particular event such as a tachycardia occurs, stimulation is stopped and the event evaluated. The operator should be ready to respond to the event appropriately, depending on the effect that the event has on the patient. For example, induction of a sustained tachycardia may result in severe hypotension, angina, or loss of consciousness. In such circumstances, expeditious termination of the tachycardia is indicated through overdrive pacing or cardioversion. The operator should also be ready to perform pacing or other maneuvers to further assess the mechanisms and re-entrant circuit of the induced tachycardia.

V. ATRIAL STIMULATION

A. An atrial study is an integral part of EPSs. The only time an atrial study is not performed is in the presence of persistent atrial fibrillation.

1. **Burst atrial pacing** at incremental rates causes slowing of AV nodal conduction (a process known as decremental conduction) and can induce tachycardia, including AV node re-entry tachycardia and AV re-entrant tachycardia. Other forms of tachycardia unrelated to AV nodal conduction can also be induced, such as atrial flutter, atrial fibrillation, atrial tachycardia, and certain forms of idiopathic ventricular tachycardia.
2. Burst pacing is performed by means of **continuous pacing** (e.g., 10 to 20 stimuli) at a fixed cycle length starting at 100 milliseconds below the baseline cycle length. Repeat burst pacing is performed at progressively shorter cycle lengths until 1:1 conduction through the AV node is no longer maintained. The shortest cycle length showing consistent 1:1 conduction through the AV node is recorded. This is related to the **effective refractory period** of the AV node, which is the longest A_1–A_2 interval that fails to be conducted to the His bundle. Another interval that can be measured is the **functional refractory period** of the AV node: it is defined as the shortest output interval from the AV node to the His bundle, given any input signal.
3. If a patient is believed to have **atrial flutter** or **atrial tachycardia**, repeat burst pacing at even shorter cycle lengths is performed until 1:1 atrial capture is no longer maintained.

B. Another form of atrial stimulation that is performed is paced extra stimulus.

1. The **effect of atrial premature beats** on the AH interval is assessed. The normal response of the AH interval is to progressively prolong with shorter A_1A_2 coupling. This is a direct demonstration of the normal decremental conduction properties of the AV node.
2. At a critical A_1A_2, the AV node fails to conduct, and on the His electrogram an atrial signal is seen without a His or ventricular deflection. This indicates that a **block has occurred in the AV node**. It is important to continue stimulation until the atrial refractory period is reached because a gap phenomenon may occasionally exist as a result of dual AV nodal pathways.
3. The **gap phenomenon** is demonstrated by apparent achievement of the AV nodal refractory period followed by resumption of conduction at shorter A_1A_2 coupling intervals. It reflects functional differences in conduction velocity or refractoriness in several regions of the AV junction.
4. If **narrow complex tachycardia** is induced, it is evaluated with regard to type, mechanism, response to maneuvers, and method of termination (see Section **IX.B.3**).

C. Sinus node evaluation. For patients who may have underlying sinus node dysfunction, sinus node tests are sometimes performed.

1. **Sinus node recovery time (SNRT)** is evaluated through burst pacing at various cycle lengths in the atrium for 30 to 60 seconds, followed by abrupt termination of pacing. SNRT is the escape interval between the last paced atrial beat and the first atrial recovery beat. A **corrected sinus node recovery time (CSNRT)** is calculated by means of subtracting the baseline sinus cycle length from SNRT. A normal value for CSNRT is < 550 milliseconds. SNRT is used to evaluate the automaticity mechanism of the sinus node.
2. **Sinoatrial conduction time (SACT)** is a combined measure of conduction in the atrial tissue that includes the area of the sinus node and sinus node automaticity. The assumptions are first that the conduction times into and out of the sinus node are equal, second that the pacing train does not alter the automaticity of the sinus node, and third that the pacemaking site does not change after premature stimulation. The SACT is measured with one of two methods.
   a. In the **Strauss method**, a sensed premature atrial beat is used to reset the sinus node, and the return cycle length after the premature beat is measured. The basic cycle length is subtracted from the return cycle length, leaving out

the time necessary to penetrate and leave the sinus nodal tissue. SACT is one-half this interval.

b. In the **method proposed by Narula**, the same measurements are obtained after pacing for eight beats at a rate slightly faster than the sinus rate. The upper range of SACT is 100 to 120 milliseconds.

The sensitivity of each individual (SACT and SNRT) test in diagnosing sinus node dysfunction is approximately 50% when used alone and 65% when combined. The specificity of the two combined tests is 88%, which gives the test a high positive predictive value. However, because of its low sensitivity, a normal test does not exclude sinus node disease.

VI. VENTRICULAR STIMULATION

A. Ventricular stimulation is performed in evaluations of suspected SVTs or ventricular tachyarrhythmias. Some SVTs, such as unusual forms of AV nodal re-entry, may be more easily induced with ventricular stimulation. To further characterize the tachycardia, the response of the tachycardia to premature ventricular beats can be assessed.

1. When ventricular stimulation is performed for the evaluation of ventricular or wide complex tachyarrhythmias, **pacing at two or more sites** maybe necessary. These sites are typically the RV apex and the RV outflow tract.

2. Before programmed stimulation is begun, pacing thresholds are determined, and the output of the pacing stimulus is set to twice the diastolic capture threshold. Higher outputs or coupling intervals shorter than 200 milliseconds may cause induction of nonclinical arrhythmias.

B. **Burst pacing in the right ventricle** is one of two techniques used when assessing retrograde ventriculoatrial (VA) conduction in the evaluation of SVT.

1. The presence of **retrograde atrial activation** is documented, and a sequence or pattern of atrial activation is evaluated.

2. The **earliest atrial activity** during retrograde conduction via the AV node is typically recorded on the His electrogram (see Fig. 53.2). This indicates that retrograde conduction has proceeded through the AV node fast pathway. **Absence of VA conduction**, with rare exceptions (e.g., the Mahaim type of accessory pathway which only conducts in the antegrade direction), excludes the presence of a bypass track. The **presence of eccentric atrial activation** (late atrial activation on the His electrogram; see Fig. 53.3) suggests the presence of a retrogradely conducting bypass track.

3. For some patients with no evidence of retrograde VA conduction, infusion of low doses of **isoproterenol** or a small dose of atropine (0.5 mg) restores this property to the AV node.

4. The **shortest paced cycle length** capable of 1:1 conduction to the atrium is documented.

C. Premature ventricular stimulation is another technique used to evaluate retrograde conduction properties of the heart.

1. If **retrograde conduction** is present, the refractory periods of the conducting pathways are determined with the extra stimulus technique.

2. In patients with **retrograde VA conduction through the AV node**, conduction block of a ventricular premature beat frequently occurs in the His-Purkinje system rather than in the AV node. His-Purkinje conduction block is more likely to occur at long drive trains. Such drive trains therefore are more likely to induce AV re-entry tachycardia (using a bypass track) by facilitating retrograde His-Purkinje block and allowing a retrograde conducted beat through the pathway to propagate antegrade through the AV node.

D. In patients being evaluated for **ventricular arrhythmias**, programmed stimulation with extra stimuli is the initial technique used. Pacing at two drive train cycle lengths (e.g., 600 and 400 milliseconds) is performed with single, double, and triple extra stimuli. Simultaneous atrial pacing at the same drive train cycle length is sometimes necessary to avoid competition from the intrinsic atrial pacemaker.

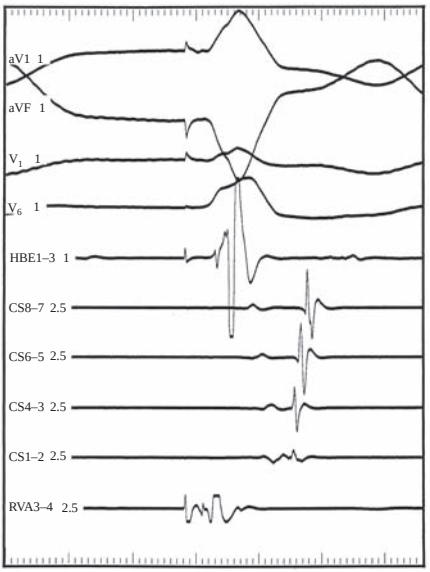

FIGURE 53.3 This is an example of a 17-year-old patient with left lateral manifest pathway. Ventricular stimulation results in retrograde atrial activation, with the earliest A seen in CS1–2 (eccentric atrial activation). CS, coronary sinus; HBE, His bundle electrogram; RVA, right ventricular apex.

E. Like the A_1A_2 technique described earlier, **V_2 is introduced at progressively shorter coupling intervals** (V_1V_2) until V_2 no longer captures (ventricular refractory period). Then V_2 is set at a coupling interval longer than the refractory period and **V_3 is introduced** at progressively shorter coupling intervals until it no longer captures. The use of **triple extra stimuli** (V_3V_4) is usually reserved for patients being evaluated for ventricular arrhythmias.

A pause of 4 to 5 seconds is allowed after each cycle to assess response and for the patient to recover after ventricular pacing. An increase in the number of extra stimuli increases the sensitivity of the study in reproducing clinical arrhythmias, but at the cost of a lower specificity due to initiation of polymorphic ventricular tachycardia or ventricular fibrillation.

If programmed stimulation with ventricular extra stimuli does not induce ventricular tachycardia in a patient at very high risk, other techniques may be used. One is **burst pacing in the ventricle**. A series of 10 paced ventricular beats are introduced at a constant cycle length. The paced cycle length is then decreased by 50 to 100 milliseconds in successive bursts until reaching within 50 milliseconds of the predicted refractory period of the right ventricle, when the decrements proceed at 10-millisecond intervals until 1:1 capture is no longer maintained. Burst pacing in the atrium can at times induce idiopathic LV tachycardia in susceptible persons.

F. In some patients, particularly those with underlying dilated cardiomyopathy, **bundle branch re-entry (BBR) tachycardia** (see Fig. 53.4) may be induced.

1. This type of tachycardia usually involves the right bundle branch as the antegrade limb and the left bundle branch as the retrograde limb of the re-entrant circuit. It is usually a rapid and hemodynamically unstable tachycardia.
2. Because His bundle refractoriness increases after a pause, a short–long–short stimulation sequence can be used to cause retrograde block in the right bundle so that the paced stimulus can conduct retrograde up the left bundle branch and possibly initiate tachycardia if the right bundle branch is no longer refractory for antegrade conduction.

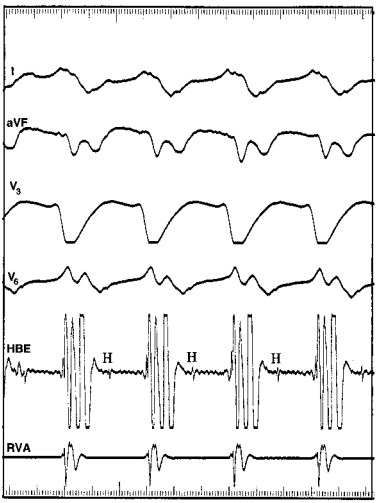

FIGURE 53.4 Bundle branch re-entry tachycardia. This example is from a 52-year-old man with dilated cardiomyopathy who presented with syncope. This ventricular tachycardia exhibits left bundle branch block morphology, and there is an H deflection preceding every V on the His electrogram. To be absolutely certain of this diagnosis (as opposed to myocardial ventricular tachycardia with retrograde His), one has to look for cycle length variation and document that changes in the H–H interval precede changes in the V–V interval. HBE, His bundle electrogram; RVA, right ventricular apex.

3. The sequence most commonly used consists of a 6-beat drive train at 400 milliseconds followed by V_2 coupled at 600 to 700 milliseconds. V_3 is then introduced at a coupling interval 100 milliseconds longer than the refractory period of the ventricle. V_2V_3 is progressively decreased until V_3 no longer captures. V_4 can be introduced if necessary.

VII. INDUCTION OF VENTRICULAR FIBRILLATION. Under certain circumstances, the operator may decide that induction of ventricular fibrillation is necessary. This is of value when testing implantable defibrillators for detection of arrhythmias and during assessment of defibrillation thresholds. Ventricular fibrillation can be induced by means of direct application of alternating current or rapid ventricular pacing at high output. The current can be delivered through a catheter electrode or through the **implantable cardioverter–defibrillator (ICD)** lead. Another means of inducing ventricular fibrillation is to deliver a low-energy shock (around 1 J) via the intracardiac leads at the peak of the T wave.

VIII. USE OF CARDIOACTIVE DRUGS DURING EPSs. Cardioactive drugs can be used during EPSs as diagnostic or therapeutic agents. The drugs most commonly used are isoproterenol, procainamide, atropine, and adenosine.

A. Isoproterenol in doses ranging from 0.5 to 5 μg/kg/min is used during EPSs to facilitate induction of SVTs and ventricular tachyarrhythmias.

1. For patients with SVTs that are AV node dependent, isoproterenol facilitates conduction through the AV node by means of shortening its refractoriness.
2. It is not absolutely certain how isoproterenol facilitates induction of ventricular tachycardia, but possible mechanisms include enhanced conduction, altered refractoriness, and enhanced automaticity related to delayed afterdepolarization.
3. Isoproterenol is particularly useful in evaluating patients with exercise-induced ventricular tachycardia and patients with the special type of RV outflow tract tachycardia. Isoproterenol is contraindicated in the presence of critical coronary artery disease.
4. Adrenergic stimulation with high doses of isoproterenol (up to 20 μg/min) also effectively induces repetitive rapid discharges from the pulmonary veins that frequently trigger initiation of atrial fibrillation (see Section **IX.B.3**).

B. Procainamide is used less frequently during EPSs. Among patients believed to have advanced underlying conduction disease, the response of the infranodal conduction system to procainamide infusion (10 to 15 mg/kg) is assessed during sinus rhythm and with atrial pacing.

1. Considerable prolongation of the HV interval or induction of infranodal block with atrial pacing at cycle lengths longer than 400 milliseconds is considered by many experts to be evidence of His-Purkinje disease. Procainamide can facilitate the induction of atrial and ventricular arrhythmias by means of slowing conduction.
2. Procainamide is often used to prevent recurrent atrial fibrillation when programmed atrial stimulation is necessary. An example would be a patient with atrial flutter who is being evaluated for ablation and is easily induced into atrial fibrillation during programmed stimulation.
3. Procainamide was widely used in the past for risk assessment among patients with inducible ventricular tachycardia. Studies have shown that patients with suppressible ventricular tachycardia have better long-term prognosis (lower rate of clinical recurrence and lower mortality) than those with non-suppressible ventricular tachycardia. However, with wider use of ICDs and evidence of their superiority even among persons with suppressible ventricular tachycardia, this application of procainamide may be of historical interest only.

C. Adenosine, in doses that produce transient AV block (6 to 18 mg), is used frequently in EPSs of patients with SVTs to define the mechanism of the tachycardia, establish AV node dependence, or document the presence or absence of accessory pathway conduction before and after RF ablation. It may also be used after atrial fibrillation ablation to assess inducibility of atrial fibrillation.

IX. INTERPRETATION OF FINDINGS IN EPSs

A. Bradyarrhythmia evaluation. EPSs are *not* indicated when symptomatic bradycardia is documented. Among patients who have a clear indication for implantation of a permanent pacemaker, findings of EPSs are unlikely to alter that decision. However, EPSs are more helpful to patients believed to have underlying **sinus node or conduction system disease and symptoms** but for whom noninvasive monitoring has failed to document a correlation between bradycardia and symptoms. EPSs are also helpful in assessing patients who continue to have symptoms after permanent pacemaker implantation.

1. **Baseline evaluation.** Sinus bradycardia, sinus arrest with junctional or ventricular escape, various degrees of heart block, and intraventricular conduction delay, isolated or in various combinations, may occur among patients with bradycardia and can be further evaluated by examining the intracardiac recordings.
   a. **Conduction intervals** are measured and evaluated. Disease in the AV node often produces prolongation in the AH interval, whereas disease in the infranodal conduction system produces prolongation in the HV interval.
   b. A long HV interval is suggestive but not diagnostic of an underlying bradyarrhythmia. It is commonly associated with wide QRS on surface ECG. A long HV interval at rest can be considered an indication for prophylactic pacemaker implantation (class IIa) if it exceeds 100 milliseconds.
   c. Documentation of intermittent spontaneous infranodal block or infranodal block in response to atrial pacing (see Fig. 53.5) or upon administration of procainamide is an indication for implanting a permanent pacemaker.
2. **Programmed stimulation**
   a. After baseline intervals are measured, **SNRT and SACT** are determined. SNRT is used to evaluate automaticity of the sinoatrial node.
   b. Rapid pacing causes overdrive suppression of the sinus node. Among patients with sinus node dysfunction, recovery time after cessation of pacing is

FIGURE 53.5 Infrahisian block in response to slow atrial pacing. This tracing is from a 70-year-old man who presented with syncope. Baseline H–V was 110 milliseconds. As shown in this tracing, burst pacing in the right atrium at cycle length of 700 milliseconds resulted in intermittent infrahisian block (H deflections not followed by V). This patient had a dual-chamber pacemaker implanted. HBE, His bundle electrogram; RVA, right ventricular apex.

prolonged. The situation is similar to sudden termination of atrial fibrillation, which can be followed by a prolonged post-conversion pause.

c. After cessation of pacing, the **longest SNRT following pacing at varying cycle lengths and secondary pauses** is documented. Secondary pauses are those intervals related to the sinus beats that occur after the first escape beat. CSNRT, which is calculated by means of subtracting baseline cycle length from SNRT, is considered abnormal if it exceeds 550 milliseconds.

d. **SACT** is used to evaluate conduction velocities in the atrium and in tissues surrounding the sinoatrial node. SACT is performed with the methods described earlier. A normal SACT is between 50 and 125 milliseconds. When both CSNRT and SACT are normal, symptoms are uncommon. The sensitivities of CSNRT (54%) and SACT (51%) combined are higher (64%), and the specificity is approximately 88%. The low sensitivity of these tests limits their value in predicting development of symptoms in asymptomatic patients.

e. **AV node and infranodal conduction system integrity** is tested with atrial stimulation techniques. Attention is paid to the AH and HV intervals during atrial pacing.

(1) The refractory period of the AV node is determined at two cycle lengths. The shortest cycle length with 1:1 AV conduction is also determined.

(2) The normal AV nodal response to burst pacing at short cycle lengths is second-degree Mobitz I AV block. HV interval prolongation or infrahisian block is not typically observed. If it occurs at cycle lengths longer than 400 milliseconds, HV interval prolongation suggests significant underlying His-Purkinje disease.

(3) Prolongation of the AV nodal refractory period is most frequently caused by high vagal tone or concomitant use of medications. It has no predictive or diagnostic value in evaluating patients believed to have bradycardia. However, a long AV nodal refractory period may mask underlying abnormal His-Purkinje refractoriness, and enhancement of AV nodal conduction with atropine or isoproterenol may be necessary during EPSs.

3. **Carotid sinus massage** is performed in all patients undergoing evaluation of bradycardia or syncope.

a. Firm pressure is applied over the carotid artery pulsation, behind the angle of the mandible.

b. A **positive cardioinhibitory response** is present if pauses of 3 seconds or more occur. A **vasodepressor response** is present if blood pressure decreases by > 50 mm Hg in the absence of marked bradycardia. Mixed responses are common.

B. SVT evaluation. One of the most important elements in the evaluation of tachyarrhythmias is careful analysis of the surface ECG during clinical tachycardia. This can give several clues to the underlying diagnosis and make the EPS more focused. Most SVTs that are induced in the EPS laboratory are re-entrant. They include AV nodal re-entry tachycardia, orthodromic AV re-entry tachycardia, atrial flutter, and re-entrant atrial tachycardia. Automatic tachyarrhythmias are relatively uncommon except in acutely ill patients. They characteristically exhibit a warm-up phenomenon and are difficult to induce with extra stimulus techniques, but may be induced with drugs such as isoproterenol.

1. **Baseline evaluation**
   a. Resting ECG and intracardiac recordings can provide important information about a possible cause even before any tachycardia is induced. The presence of a short PR interval on the ECG and wide QRS complex with a slurred initial deflection suggests preexcitation.
   b. Absence of preexcitation at rest does not rule out the presence of an accessory pathway. For the diagnosis of SVT, an atrial and a ventricular study have to be performed.
   c. If tachycardia is not induced at the baseline study, programmed stimulation in the atrium and ventricle is repeated with isoproterenol.
   d. Some SVTs, particularly those involving AV re-entry using a bypass tract, can be induced with ventricular stimulation, whereas atrial flutter and, to a lesser extent, atrial tachycardia are rarely induced by means of ventricular stimulation.
2. **Programmed stimulation** begins with burst pacing in the ventricle to document and characterize VA conduction. Absence of VA conduction practically excludes a concealed bypass tract, and ventricular extra stimulus technique may not need to be performed unless ventricular tachycardia is suspected.
   a. **Earliest retrograde atrial activity** is usually seen on the His electrogram during normal retrograde atrial activation through the AV node. Early retrograde atrial activity on the distal CS electrogram, if the position of the CS catheter is correct, suggests the presence of a left-sided accessory pathway (see Fig. 53.4). Early atrial activity in the proximal CS electrodes suggests a posteroseptal pathway or AV node slow pathway conduction.
      (1) Eccentric atrial activation is any atrial activation that does not activate the AV node and the area around the AV node first. This is frequently seen with retrograde ventricular stimulation, when the retrograde impulse finds the AV node refractory. The site of earliest atrial activation is then in the distal CS catheter and not in the proximal area closest to the AV node/His bundle. Evidence of eccentric atrial activation may not be clear during burst pacing when there is fusion of retrograde impulses, arriving through both the AV node and the accessory pathway.
      (2) The retrograde 1:1 cycle length should be documented.
      (3) Programmed ventricular stimulation is performed with single premature beats at two drive train cycle lengths (e.g., 600 and 400 milliseconds). During programmed stimulation, the following are recorded:
         (a) Retrograde refractory periods
         (b) The pattern and any changes in retrograde atrial activation
         (c) The site of retrograde VA block
         (d) The presence of dual retrograde AV node function
      (4) If an accessory pathway is found, its retrograde 1:1 conduction cycle length and refractory period are documented.

b. During atrial stimulation, particular attention is paid to the **AH and HV intervals.**

(1) Sudden prolongation of A_2H_2 of > 50 milliseconds in response to a decrement of 10 milliseconds in A_1A_2 is called a **jump** (see Fig. 53.6) and has been classically described as a sign of dual AV nodal physiology. **However, more recent reports have demonstrated that the normal AV node has dual pathways even if this "jump" is not demonstrated.** Furthermore, initiation of AV nodal re-entrant tachycardia does not require the presence of such a jump in the AV nodal conduction curve.

(2) Induction of re-entrant tachycardias generally depends on the occurrence of **unidirectional block and conduction delay**. In the case of AV nodal re-entry, antegrade block in the fast pathway combined with critical delay in the slow pathway allows the impulse to conduct retrograde on the fast pathway and excite the atrium. This first retrograde-conducted atrial depolarization is called an **echo beat** (see Fig. 53.6). If this echo beat succeeds in conducting antegrade down the slow pathway again and retrograde up the fast pathway, sustained AV nodal re-entry occurs.

(3) **Induction of AV node re-entry** is facilitated by use of shorter drive train cycle lengths and, if necessary, use of more than one extra stimulus or rapid burst atrial pacing. Occasionally, initiation of AV nodal re-entry requires ventricular pacing or premature beats.

(4) In the presence of an accessory pathway, the site of critical delay is also in the AV node. However, to induce orthodromic AV re-entry tachycardia, antegrade block of an atrial impulse has to occur in the accessory pathway so that it is excitable by the time the same impulse propagates

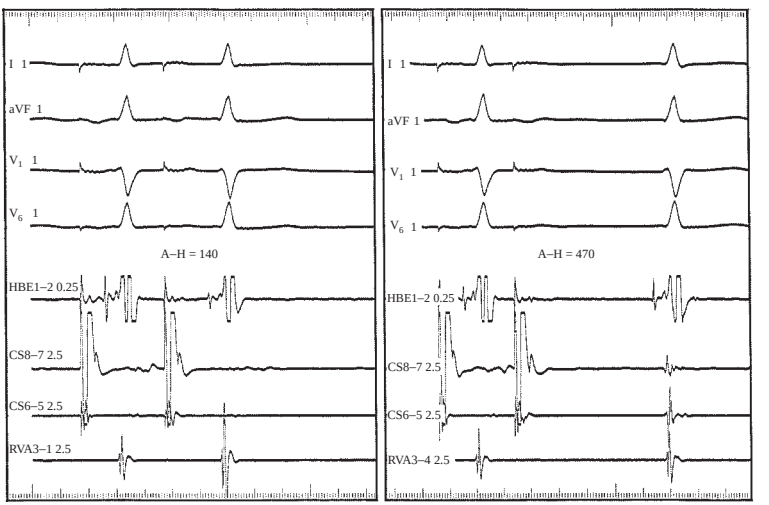

FIGURE 53.6 AV nodal jump and echo. A 10-millisecond decrement in S_1S_2 resulted in marked prolongation of A_2H_2 by > 300 milliseconds. In addition, an echo beat with a short H–A is seen on the CS electrogram, a definite evidence of dual AV node physiology. The atrial premature beat, blocked antegrade in the fast pathway, was conducted with sufficient delay in the slow pathway to encounter a nonrefractory retrograde fast pathway. AV, atrioventricular; CS, coronary sinus; HBE, His bundle electrogram; RVA, right ventricular apex.

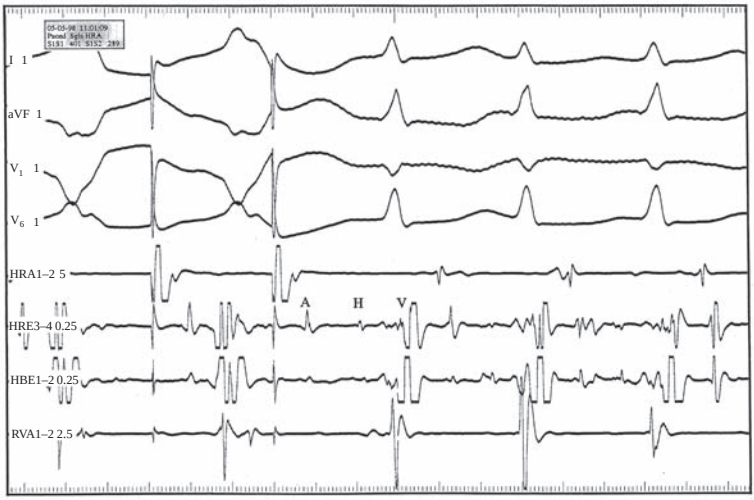

FIGURE 53.7 Orthodromic AV re-entry tachycardia. In this example from a patient with a manifest right-sided accessory pathway, premature atrial stimulation (S) blocks in the accessory pathway (resulting in a narrow QRS complex), conducts with a longer A–V, and re-excites the atrium. The tachycardia is narrow complex, with an H–A interval of 180 milliseconds. The earliest A is seen on the high right atrial catheter. AV, atrioventricular; CS, coronary sinus; HBE, His bundle electrogram; RVA, right ventricular apex.

through the AV node and ventricle and arrives to conduct retrogradely through the accessory pathway to the atrium (see Fig. 53.7).

3. **Evaluation of induced tachycardia**
   - **a.** If a tachycardia is induced, the first assessment is its **hemodynamic consequences**. Hemodynamically unstable tachycardia should be immediately terminated. Only if the tachycardia is hemodynamically stable can further evaluations during tachycardia be conducted.
     - **(1)** Whether the QRS is narrow or wide, the relation between atrial rate and ventricular rate is noted (AV association or dissociation).
     - **(2)** Lack of a 1:1 AV relation excludes AV re-entry tachycardia and, for practical purposes, AV nodal re-entry. In rare instances, AV node re-entry tachycardia can exhibit 2:1 AV block.
     - **(3)** If the atrial rate is faster than the ventricular rate, the diagnosis is **atrial tachycardia or atrial flutter**, depending on the rate and pattern of atrial activation.
     - **(4)** If the ventricular rate is faster than the atrial rate, the diagnosis is ventricular tachycardia. Alternative causes for AV dissociation include AV nodal re-entry tachycardia with block in the upper common pathway, re-entry tachycardia with a nodofascicular pathway, or a junctional tachycardia with retrograde block.
   - **b.** When a **1:1 AV relation** exists, **further evaluation** is needed. The following observations and techniques are helpful in arriving at the most likely mechanism:
     - **(1) Atrial activation.** The sequence of atrial activation during tachycardia is important in the differential diagnosis of SVT. Accurate placement of catheters is extremely important; catheter misplacement can lead to

inappropriate conclusions or interventions. The **earliest site of atrial activation** is noted. As mentioned above, if earliest atrial activation is in the distal CS, a left atrial tachycardia or AV re-entry using a left-sided accessory pathway is most likely. If an accessory pathway is located in the posterior septum, the earliest A is seen in the proximal CS electrogram. This is also true if the atria are being activated through the slow pathway of the AV node, as in atypical AV nodal re-entry tachycardia.

(2) The presence of **cycle length variation** during tachycardia helps predict the activation sequence. For example, a change in AA coupling interval before an equal change in HH or VV interval (with changing VA) suggests a diagnosis of atrial tachycardia.

(a) In cases of wide complex tachycardia in which there appears to be a 1:1 relation between H and V, HH interval change preceding VV interval change suggests supraventricular or BBR tachycardia.

(b) Cycle length variation may also be helpful when there is **slowing of tachycardia with the development of bundle branch block and acceleration with resolution of the block**. This finding is suggestive of AV re-entry using an accessory pathway ipsilateral to the bundle branch block as the retrograde limb. This can be appreciated on the surface ECG. In fact, prolongation in tachycardia cycle length in association with a bundle branch block is caused by prolongation of the VA interval. The activation wavefront must travel down the contralateral bundle and across the intraventricular septum before it reaches the pathway. The change in cycle length is more pronounced with lateral than with septal pathways.

(3) HA and VA intervals. A constant HA or VA relation despite cycle length variation (even in the absence of bundle branch block) is highly suggestive of **AV node re-entry or accessory pathway–mediated tachycardia.** The change in tachycardia cycle length is caused by varying antegrade conduction time through the AV node. The VA time can also be used to differentiate AV nodal re-entry from AV re-entry. A VA interval < 70 milliseconds is rarely seen with AV re-entry and strongly suggests the diagnosis of AV nodal re-entry (see Fig. 53.8). VA times in excess of 70 milliseconds are seen with AV re-entry and atypical AV nodal re-entry (so-called fast–slow AV nodal re-entry).

(4) Introduction of premature beats during tachycardia. Premature ventricular beats are typically introduced during tachycardia at intervals when the His bundle is refractory. Because the normal retrograde path (His-AV node) is refractory, preexciting the atrium with a premature ventricular beat at those intervals is diagnostic of the presence of an accessory pathway capable of retrograde conduction. Consistent termination of tachycardia with such premature beats without retrograde conduction to the atrium is also diagnostic of AV re-entry and excludes atrial tachycardia.

(5) Pacing maneuvers during SVT. During SVT, ventricular pacing maneuvers can be a useful first step in diagnosing the mechanism of tachycardia. Ventricular pacing at a cycle length slightly faster than the tachycardia cycle length is referred to as ventricular overdrive (VOD) pacing. Successful entrainment occurs when VOD resets the tachycardia such that the atrial rate is accelerated to the paced ventricular cycle length and returns to the tachycardia cycle length when ventricular pacing stops and the tachycardia continues. An atrial–atrial–ventricular response upon cessation of VOD, or V–A–A–V response, is diagnostic of atrial tachycardia. A V–A–V response is most consistent with a re-entry tachycardia. The relationship of the post-pacing interval to the tachycardia

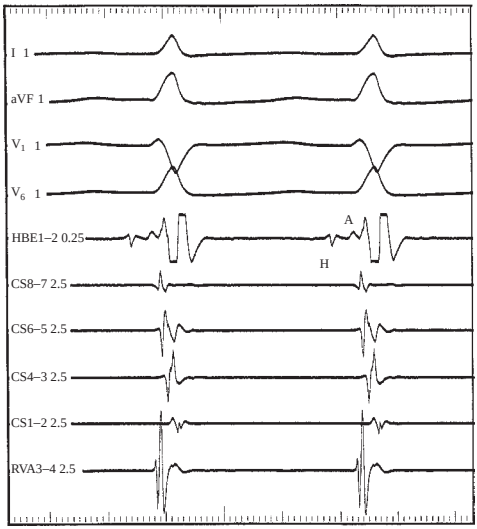

FIGURE 53.8 AV node re-entry tachycardia. Tachycardia is narrow complex and characterized by very short V–A interval and an H–A interval of < 70 milliseconds. AV, atrioventricular; CS, coronary sinus; HBE, His bundle electrogram; RVA, right ventricular apex.

cycle length can then be helpful in differentiating the type of re-entry tachycardia.

(6) Initiation and termination of tachycardia. To understand the mechanism of tachycardia, it is important to know the mechanism of initiation. For re-entry to occur, block in one limb of the re-entrant circuit and slow conduction in the other limb must take place. It is important to review the stimulation sequences that did not induce tachycardia and compare them with those that did. A sudden jump in the AH interval suggests, but is not diagnostic of, AV nodal re-entry. Orthodromic AV re-entry tachycardia develops during atrial stimulation after antegrade block in the accessory pathway takes place in combination with a critical delay in the AV node. With ventricular stimulation, AV re-entry tachycardia develops after block in the AV node or His-Purkinje system occurs. Termination of the tachycardia simultaneous with AV node block (A with no H) suggests AV node dependence and is helpful in excluding AV node–independent tachycardias (atrial tachycardia and flutter).

4. **Significance of induced tachycardia.** With the exception of atrial fibrillation, induced re-entrant SVTs signify the presence of an established anatomic circuit. Comparison with the clinical arrhythmia is important and, unless significant differences exist, it can safely be assumed that the induced tachycardia is clinically significant. If a wide complex tachycardia with a supraventricular mechanism is induced, the recording is compared with a clinical recording. If the QRS morphology is different from that of the clinical arrhythmia, a search for ventricular arrhythmia may be warranted.
5. **Atrial flutter**, a special type of atrial tachycardia that involves a well-defined anatomic circuit, is amenable to curative catheter ablation techniques.
   a. In the typical variety of atrial flutter, the waveform travels counterclockwise around the tricuspid annulus. The circuit is bounded anteriorly by the tricuspid annulus and posteriorly by the crista terminalis and its inferior medial continuation as the eustachian ridge. The site of functional block appears to be in the isthmus region, which is the narrow corridor between

the inferior tricuspid annulus and the inferior vena cava. The site of conduction delay or slowing appears to be due to transverse conduction block into the crista, forcing the wavefront to enter the crista at its superior end before propagating down the crista into the isthmus region.

b. To induce counterclockwise atrial flutter, progressively more rapid (approximately 250 to 200 milliseconds) burst pacing appears to be most successful and is performed anywhere medial to the isthmus. The impulses block in the isthmus and conduct counterclockwise around the tricuspid ring with sufficient delay to sustain atrial flutter. If burst pacing is used lateral to the isthmus, clockwise atrial flutter may be induced. Successful ablation of typical atrial flutter necessitates generation of bidirectional isthmus block by applying a line of RF lesions that spans the posterior isthmus from the tricuspid valve to the inferior vena cava (the cavotricuspid isthmus).

c. Less commonly, different types of atrial flutter in which the subeustachian isthmus is not part of the circuit are induced. These atypical flutters have many varieties and locations but share a common re-entrant circuit that revolves around an area of conduction block or delay, usually scar tissue. Treatment involves creating an ablation line from the area of scar to an anatomic barrier or ablating critically narrowed re-entrant paths within a scarred region. The success rates in ablating these atypical forms of atrial flutter are not as high as for isthmus-dependent flutters.

6. Atrial fibrillation. Previous evidence favored multiple re-entrant wavelets as the predominant mechanism responsible for atrial fibrillation. However, it has been recently demonstrated that atrial fibrillation is frequently initiated by rapidly firing foci located predominantly in the pulmonary veins, where sleeves of atrial muscle with abnormal automaticity or perhaps re-entry are present. Our current concept of atrial fibrillation revolves around two factors: a triggering mechanism and a substrate that can maintain atrial fibrillation. Most atria, especially in relatively normal hearts, are quite resistant to initiation of atrial fibrillation. Thus, the concept of focal initiation of atrial fibrillation by rapid bursts of focal atrial tachycardia emerged as a triggering mechanism, making it possible to map and target these sites for catheter ablation. The current understanding is that a vast majority of these triggering sites are near the os of the pulmonary veins in the left atrium.

a. Ablation of these triggering foci requires left atrial access by transseptal puncture. Following transseptal puncture, a decapolar mapping catheter with a ring configuration called a lasso is used to record electrical activity around the circumference of each pulmonary vein ostium. It displays a far-field atrial signal and a near-field pulmonary vein potential. This is characterized as a very sharp spike following the atrial deflection during sinus rhythm. However, discharges from the vein will invert this activation sequence; the pulmonary vein potential will precede the atrial activation.

b. RF ablation is delivered around the roving circular lasso catheter along the antrum of the pulmonary veins to abolish the pulmonary vein potentials. Alternatively, a wide antral circumferential ablation around the pulmonary veins on each side is used to electrically isolate the pulmonary veins from the left atrium. In that manner, abnormal firing would be confined to the veins and no atrial fibrillation would be induced.

c. In a minority of cases, atrial fibrillation may be induced by rapid discharges originating from nonpulmonary vein foci, most commonly from the superior vena cava. Circumferential catheter ablation can be performed in the same fashion, aiming at abolition of all venous potentials (electrical isolation).

C. Evaluation of accessory pathways

1. The **most common locations** for accessory pathways in decreasing order of frequency are left free wall, posterior region, posteroseptal region, right free wall,

and anteroseptal region. Concealed accessory pathways (no evidence of antegrade conduction) with only retrograde conduction are more common than manifest pathways, which have antegrade conduction manifested by delta waves on the surface ECG, the slurred initial deflection of the QRS that implies preexcitation as described earlier.

   a. **Right-sided accessory pathways** are more likely than left-sided accessory pathways to be associated with **congenital heart disease**. An unusual type of right-sided accessory pathway is the atriofascicular accessory pathways, which originate in the right atrium, traverse the right anterior region of the tricuspid valve annulus, and insert in the region of the right bundle or the right-sided Purkinje network. These accessory pathways have unidirectional antegrade conduction with decremental conduction properties similar to an AV node. These pathways are frequently referred to as Mahaim pathways and typically do not conduct retrogradely.
   b. **Multiple accessory pathways** are more frequently encountered on the right side and in survivors of sudden death. In these patients, the most common combination is posteroseptal and right free wall pathways.
   c. Both antidromic and orthodromic AV re-entrant tachycardias require participation of the accessory pathway. In rare instances, antidromic tachycardia can involve one accessory pathway in the antegrade direction and a second pathway in the retrograde direction.

2. Evidence of preexcitation is supported by the presence of **short HV interval** (< 35 milliseconds) **at rest** or with atrial pacing and the appearance of increasing preexcitation either with atrial pacing or with administration of drugs that cause AV nodal conduction slowing, or with autonomic maneuvers. The electrophysiologic properties of the accessory pathway are examined, including its antegrade and retrograde conduction and refractory periods. If tachycardia is induced during atrial or ventricular stimulation, its mechanism is defined according to the techniques discussed earlier. This depends on whether the tachycardia is narrow or wide complex.
3. **Orthodromic AV re-entry tachycardia** is commonly initiated by a ventricular premature stimulus that blocks in the His-Purkinje system or, rarely, in the AV node, but conducts in a retrograde direction over the accessory pathway. It can also be induced by an atrial premature stimulus (echo beat) that blocks the accessory pathway and conducts slowly over the AV conducting system. Induction is facilitated by the presence of a relatively **long antegrade refractory period of the accessory pathway** or a **long retrograde refractory period of the His-Purkinje system**.
4. **Antidromic AV re-entry tachycardia** (see Fig. 53.9) can be initiated with burst pacing in the atrium or with a premature atrial stimulus that **blocks in the AV node** and **conducts over the accessory pathway**. Less often, it can be induced with a premature ventricular stimulus that blocks the accessory pathway in a retrograde manner and conducts over the AV node. Induction of antidromic tachycardia necessitates excellent retrograde conduction over the His-Purkinje system–AV node; it almost always involves a free wall accessory pathway as the antegrade limb and is frequently associated with the presence of multiple accessory pathways.
5. **Localizing accessory pathways**
   a. **Surface electrocardiographic localization**
   (1) **Delta wave vectors**
      (a) Left lateral: negative I, aVL; positive II, III, aVF, V_1–V_6
      (b) Left posterior wall: positive I, aVL; negative II, III, aVF; positive V_1–V_3/V_4
      (c) Posteroseptal: positive I, aVL; negative II, III, aVF; R/S < 1 in V_1
      (d) Right free wall: positive I, aVL, II; negative III; biphasic V_1 and V_2
      (e) Anteroseptal: positive I, aVL; positive II > III; negative V_1–V_6

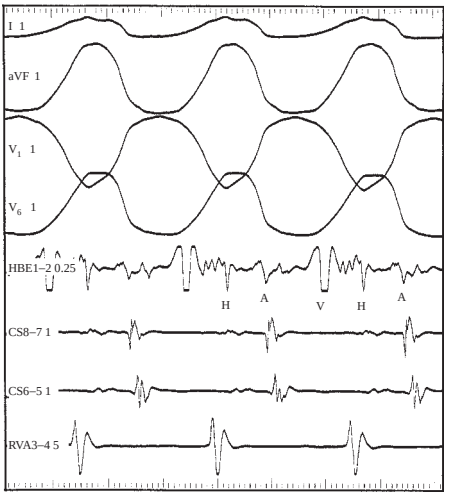

FIGURE 53.9 Antidromic AV re-entry tachycardia. This tachycardia was induced with atrial burst pacing in a young patient with two right-sided manifest accessory pathways. The tachycardia is rapid and wide complex, with the earliest retrograde A seen in HBE1–2, consistent with retrograde activation through the AV node. AV node re-entry with antegrade activation using the accessory pathway (bystander accessory pathway) was excluded by lack of evidence of dual AV node physiology. AV, atrioventricular; CS, coronary sinus; HBE, His bundle electrogram; RVA, right ventricular apex.

(2) P-wave morphology during orthodromic tachycardia
- **(a)** Left lateral: negative I, aVL; positive III > aVF > II; negative V_5 and V_6
- **(b)** Posteroseptal: positive aVR, > aVL; negative II, III, aVF
- **(c)** Right free wall: positive I, aVL, II; negative III; biphasic V_1 and V_2

b. Localization during EPSs

(1) Pacing from multiple atrial sites: shortest A-delta occurs with pacing close to the atrial insertion site of AP and results in maximal preexcitation.

(2) Retrograde atrial activation during orthodromic tachycardia and V pacing
- **(a)** Atrial activation sequence
  - **(i)** Left and right free wall: eccentric
  - **(ii)** Posteroseptal: A_{CSos} earlier than A_{His}
  - **(iii)** Anteroseptal: A_{CSos} later than A_{His}
- **(b)** Atrial activation sequence when a ventricular premature stimulus is delivered during tachycardia at the time when His is refractory
- **(c)** The earliest site of atrial activation identifies the site of atrial insertion of an accessory pathway

(3) Relation of local ventricular electrogram to delta: earliest V correlates with ventricular insertion site. This may be slightly offset or oblique compared with the atrial insertion site.

(4) Effects of bundle branch block
- **(a)** Bundle branch block increasing the VA interval by > 35 milliseconds; ipsilateral free wall accessory pathway
- **(b)** With bundle branch block ipsilateral to septal accessory pathways, the increase in VA times is < 25 milliseconds
- **(c)** Left anterior fascicular block can increase VA times 15 to 35 milliseconds with left free wall accessory pathway, particularly with an anterolateral left-sided accessory pathway

(5) Recording of accessory pathway potential: sharp spike 10 to 30 milliseconds before the onset of the delta wave

6. Identifying the presence of multiple accessory pathways

a. Changing antegrade delta waves during sinus rhythm, atrial pacing, atrial fibrillation, and with antiarrhythmic drugs

- **b.** Evidence of multiple routes of retrograde atrial activation
  - **(1)** Changing VA time or activation sequence
  - **(2)** Failure to prolong VA time with ipsilateral bundle branch block
- **c.** Orthodromic tachycardia with antegrade fusion
- **d.** Preexcited tachycardia
  - **(1)** Antegrade conduction over septal accessory pathway
  - **(2)** Antidromic tachycardia faster than orthodromic tachycardia
- **e.** Atypical patterns of preexcitation
- **f.** Mismatch of site of antegrade preexcitation and retrograde atrial activation during AV re-entry tachycardia

D. Ventricular tachycardia evaluation

1. The most common reason for performing EPS on patients with suspected ventricular arrhythmias is documentation of inducible tachycardia, testing the effect and response to anti-tachycardia pacing and defibrillation, and endocardial mapping to direct attempts at ablation. Recent trials have stratified patients with ischemic or nonischemic cardiomyopathy, congestive heart failure, and reduced LV ejection fraction at higher risk for sudden cardiac death and thus reduced the usefulness of EPS in determining the need for ICD implantation.
2. An **atrial study** is considered for all patients undergoing evaluation of ventricular tachycardia. This serves three main purposes: diagnosis of the underlying advanced conduction system disease, documentation of coexisting SVT, and induction of rare forms of ventricular tachycardia that may be inducible only with atrial pacing.
3. **Programmed ventricular stimulation** is performed as described earlier. If ventricular tachycardia is not induced despite program stimulation from two RV sites (RV apex and outflow tract), repeat stimulation can be performed after isoproterenol infusion. However, isoproterenol should not be given to patients with active ischemic heart disease. It is primarily of value to those with exercise- or catecholamine-dependent ventricular tachycardia. LV stimulation is not necessary because RV stimulation techniques have adequate sensitivity and specificity, and the risk of left heart catheterization is avoided. If no ventricular tachycardia is induced with any of these techniques, the arrhythmia is deemed noninducible.
4. **Techniques for terminating induced ventricular tachycardia.** Pacing terminates as many as 85% of induced ventricular tachycardias in the laboratory. Success is more likely to be achieved with slower tachycardia rates (< 200 beats/min) and in hemodynamically tolerated tachycardias. Other factors predictive of success of pacing include the site of stimulation in relation to the tachycardia zone, ventricular conduction properties, and refractoriness. Pacing can also accelerate tachycardia, an important consideration when anti-tachycardia pacing is being considered.
5. **Techniques for terminating tachycardia with pacing.** One technique entails use of one or more **progressively earlier premature ventricular stimuli**. The other technique uses **burst pacing** to overdrive the tachycardia, but there is a greater risk of accelerating the tachycardia into a hemodynamically unstable arrhythmia. Techniques that can be used if pacing fails include delivery of ultrarapid train stimulation and synchronized direct current cardioversion.
6. There are a variety of **responses to programmed stimulation**. What is important is the correlation between these responses in different populations of patients and future risk of adverse outcome. For example, induction of single or double BBR beats has no bearing on long-term outcome among persons with normal LV function and is not considered an abnormal finding. Induction of sustained monomorphic ventricular tachycardia, particularly among persons with reduced LV ejection fraction, identifies a subset of patients at high risk for sudden death.

a. Sustained monomorphic ventricular tachycardia

(1) Induction of sustained monomorphic ventricular tachycardia is the **most important response** and has the highest predictive value. This is particularly true if the induced tachycardia is similar to the clinical arrhythmia in both rate and structure. Patients with easily induced ventricular tachycardia (e.g., with single premature beats) have worse outcome than those in whom tachycardia is more difficult to induce. It is important to document reproducibility of ventricular tachycardia during programmed stimulation. Slow, sustained tachycardia, particularly in patients with ischemic substrate, is typically more reproducible than more rapid tachycardias and tachycardias in those with nonischemic cardiomyopathies. Sustained tachycardia has clearly worse prognostic implications than nonsustained tachycardia. There is no agreement on what constitutes an abnormal response among patients with nonsustained tachycardia or whether any therapeutic intervention should be pursued for these patients.

(2) Among patients with ischemic substrate, programmed stimulation induces sustained monomorphic ventricular tachycardia in as many as 95% of patients with a history of clinical sustained ventricular tachycardia, approximately 60% of those with nonsustained ventricular tachycardia, and approximately 50% of patients experiencing sudden cardiac death. Induction of sustained monomorphic ventricular tachycardia in any of the above subsets has very high specificity (> 90%) for spontaneous clinical ventricular tachycardia and sudden death. Testing at two RV sites increases sensitivity without sacrificing specificity.

(3) Patients with **nonischemic substrate** are more challenging to evaluate because EPSs are less sensitive and specific. Although inducible sustained monomorphic ventricular tachycardia has a worse prognosis than the noninducible type, the positive predictive value of abnormal results of EPS is at best 70%. Patients with negative results of EPS are still at high risk for sudden death, even if they have no prior clinical events. The prognosis may be more favorable if inducible tachycardia is suppressed by drugs, but the risk of future events continues to be high. One can never be reassured about the outcome among patients with nonischemic cardiomyopathy using results of EPS.

(4) **BBR tachycardia** is a type of ventricular tachycardia with a well-defined macro re-entrant circuit. It occurs most often among patients with dilated cardiomyopathy and is frequently symptomatic.

(a) In the **typical pattern**, the impulse travels antegrade down the right bundle branch, across the interventricular septum, and retrograde up the left bundle branch. The tachycardia exhibits a left bundle branch block pattern, with a **His deflection preceding every QRS complex**. In sinus rhythm, the **HV interval is abnormally long**, and during tachycardia it is at least equal and frequently longer than the baseline HV.

(b) In rare instances, it is difficult to differentiate BBR tachycardia from an SVT with aberration or from a myocardial ventricular tachycardia with retrograde His deflections.

(c) BBR tachycardia is frequently rapid and exhibits AV dissociation. If cycle length variation takes place, it is important to assess the order of changes in the HH and VV intervals. If HH changes take place before VV changes, BBR is likely. A VV change that occurs before HH change and is also associated with a variation in the HV interval suggests myocardial ventricular tachycardia.

(d) Treatment with **antiarrhythmic agents**, including amiodarone, is not helpful and may lead to stabilization of the re-entrant circuit. BBR tachycardia is curable with RF ablation of the right bundle.

b. **Polymorphic ventricular tachycardia** frequently occurs with high-output stimulation. It is also more likely to occur with increasing numbers of extra stimuli.

(1) **Interpretation** of the induction of polymorphic ventricular tachycardia depends on the clinical situation. For example, inducible polymorphic ventricular tachycardia in a survivor of sudden cardiac death is considered significant. In a patient with ventricular ectopy and normal ventricular function, inducible polymorphic ventricular tachycardia is a nonspecific response.

(2) Similar interpretation applies to **induced ventricular fibrillation**. If the patient has never had clinical ventricular tachycardia or ventricular fibrillation and has no underlying heart disease, the induced ventricular fibrillation is considered a nonspecific finding that does not warrant therapy.

c. Patients with **hypertrophic cardiomyopathy** represent another subset for whom the predictive value of EPS is problematic. Induction of sustained monomorphic ventricular tachycardia, induction of ventricular fibrillation without aggressive stimulation protocols, and induction of ventricular arrhythmias with atrial pacing or as a result of atrial fibrillation are generally considered to be **poor prognostic signs**.

d. **Summary**. It is important to have a thorough understanding of the underlying clinical problem and anatomic substrate to assess the appropriateness of any EPS finding for an individual patient.

(1) Repetitive responses caused by BBR are usually physiologic, whereas intramyocardial repetitive ventricular responses are abnormal. However, neither of these responses should be used to guide therapy.

(2) Induced polymorphic ventricular tachycardia and ventricular fibrillation can be considered nonspecific findings or clinically significant depending on the clinical circumstances. However, they should not be used to guide drug therapy in any situation.

(3) Induced sustained monomorphic ventricular tachycardia identical to the clinical arrhythmia has the highest sensitivity and specificity and has greater importance in predicting outcome.

(4) The importance of nonsustained ventricular tachycardia remains controversial. Noninducibility in patients with nonischemic cardiomyopathy or survivors of sudden cardiac death may not provide prediction as accurate as that for patients with underlying ischemic substrate and documented nonsustained ventricular tachycardia. Therapeutic decisions therefore have been individualized.

(5) Guidelines derived from studies including the MADIT trials and the SCD-HeFT have obviated the need for performing EPS before deciding to implant ICDs in particular patient populations.

7. **Mapping of ventricular tachycardia.** Mapping of ventricular tachycardia involves identification of the **earliest sites of activation** during tachycardia and detailed outlining of the **tachycardia circuit**. Endocardial mapping has aided in the evaluation of mechanisms of tachycardia. More recently, mapping has been coupled with RF ablation with high rates of success.

a. Mapping can be performed with steerable electrode catheters during EPS or can involve introduction of specialized catheters with various configurations designed to compare several simultaneously acquired endocardial electrograms.

b. For the most part, mapping of ventricular arrhythmias takes place in the left ventricle. However, several types of ventricular tachycardia that originate from the right ventricle, including those from the outflow tract, have been successfully mapped and ablated.

c. Activation mapping takes place during the tachycardia. The objective is to identify the site of earliest activation. Because this lengthy process has to take place during tachycardia, it must be hemodynamically tolerable. The earliest activation site corresponds to the exit site of the circuit.

d. Sites of origin of tachycardia in patients with ischemic heart disease are usually found in the periinfarction zone or in the border of an LV aneurysm. To confirm the site, entrainment from that site is performed. Entrainment involves transient overdrive pacing and resetting of the tachycardia without terminating the tachycardia. When entrainment is achieved within the re-entrant circuit inside the slowly conducting scarred regions of the heart, or isthmus, pacing produces QRS morphologic match on all 12 surface ECG leads. The return cycle length of activation at the site of pacing after cessation of pacing equals the tachycardia cycle length (see Fig. 53.10). These two observations imply that depolarization caused by pacing has the same exit from the scar as the tachycardia and that the pacing site is within the circuit.

e. Pace mapping can be used in evaluations of patients with hemodynamically intolerable tachycardia. Ventricular pacing is performed at various sites at rates that do not cause hemodynamic instability. The site where pacing results in QRS match with clinical tachycardia corresponds to the exit sites of the tachycardia circuit.

f. **Electroanatomic mapping systems allow the** measurement of tissue voltage, providing accurate delineation of scar tissue and its boundaries. Thus, mapping in sinus rhythm allows for delimitation of the scar and areas of the scar border that are likely sites of tachycardia exit. Pace mapping can be used to identify those sites around the scar that correspond to tachycardia exits. Linear lesions, performed to interrupt these exit sites responsible for re-entrant circuits, can be undertaken, allowing successful ablation of tachycardias that would not be otherwise mapped due to patient intolerance of any sustained tachycardia. Another method of mapping a hemodynamically unstable ventricular tachycardia is to use a mapping system that can acquire the map of the entire endocardium in a single beat. This requires insertion of an "array" catheter into the left ventricle that acquires the electrograms from 64 points on the balloon and calculates the virtual activation on the endocardial surface. Alternatively, an intra-aortic balloon pump or percutaneous LV assist device may be considered to assist with mapping and ablation during prolonged or hemodynamically unstable VT.

g. Mapping can also be performed intraoperatively when endocardial resection is considered. Although this approach can still be used, it is infrequently recommended, as other approaches described above in combination with implantable defibrillators have yielded good patient survival and excellent success in eliminating problematic ventricular tachycardias.

h. Some patients including many with nonischemic cardiomyopathy or certain variants such as Chagas disease and hypertrophic cardiomyopathy may require both endocardial and epicardial approaches to VT mapping and ablation. Percutaneous access into the epicardial space is obtained with a subxiphoid approach under fluoroscopic guidance and small injections of contrast until the parietal pericardium is penetrated. In patients with dense pericardial adhesions that may limit catheter movement, an intraoperative subxiphoid incision or open sternotomy may be considered to allow for greater exposure and access.

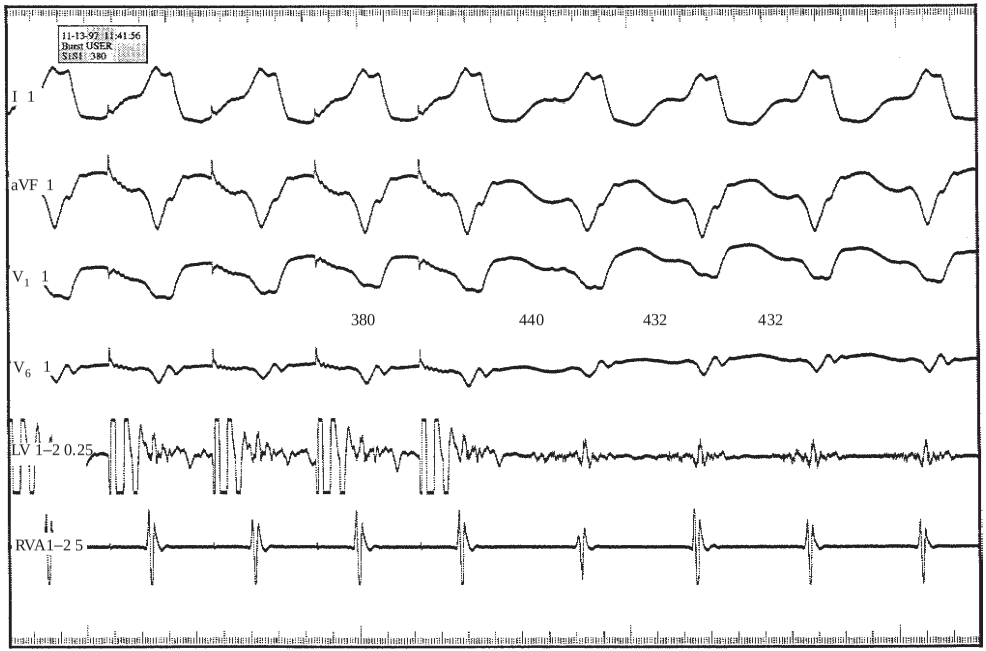

FIGURE 53.10 Entrainment of ventricular tachycardia. Pacing at a rate slightly faster (380 milliseconds) than tachycardia cycle length at a site believed to be the isthmus of the tachycardia resulted in QRS morphology very similar to the native ventricular tachycardia (concealed entrainment) in all 12 leads (only 4 leads shown). In addition, the post-pacing interval is very close to the tachycardia cycle length, suggesting that the pacing site is within the tachycardia circuit. Application of radiofrequency energy at this site resulted in successful ablation of this tachycardia. LV, left ventricular; RVA, right ventricular apex.

CHAPTER 54

Tyler L. Taigen

Cardiac Pacing

I. INTRODUCTION. The indications and technology of cardiac pacing continue to evolve, leading to a rapid increase in the number of pacemakers implanted. Pacemaker implantation rates increased from 329 implants per million population in 1990 to 612 per million population in 2002. In 2011, 400,000 cardiac devices were implanted and over 3 million people in the United States had implantable cardiac rhythm management devices. It is imperative that the physician caring for the pacemaker patient understand the basic physiology and technology of cardiac pacing and be able to apply these principles to effectively manage the unique problems with which these patients may present.

II. BASIC COMPONENTS OF CARDIAC PACEMAKERS

A. Pulse generator

1. **Power source (battery).** Lithium iodide is the most common chemical compound used. Lithium batteries deplete over a more predictable time course than other types of compounds, such as zinc mercuric oxide, that were used in prior generations of devices.
2. **Circuitry**
   a. **Output circuits.** These circuits control programmable features of the output pulse, including amplitude and pulse width.
   b. **Sensing circuits.** These circuits process the intracardiac electrogram, including amplification and filtering of the signal, and also provide other functions such as management of external electromagnetic interference (EMI). A bandpass filter allows signals of a certain frequency range to be passed while signals of other frequency ranges are blocked or attenuated. Pacemakers use a bandpass filter to distinguish between cardiac depolarization and repolarization signals from extracardiac signals, such as myopotentials from the chest wall musculature. Some appropriate signals that pass through the filter are small in amplitude, and a sense amplifier increases the appropriate signal for the device to process.
   c. **Timing circuits.** These circuits control the pacing intervals and sensing/refractory periods. They may be altered by input from the sensing circuits.
   d. **Telemetry circuit.** These circuits allow communication between an external programmer and the pulse generator for pacemaker programming or retrieval of information.
   e. **Microprocessor.** Most modern pacemakers have computer chips with memory (read only memory [ROM] and random access memory [RAM]) and therefore have enhanced capabilities, such as downloading of new features via telemetry and increased storage of diagnostic data.
   f. **Sensor circuit for rate-adaptive pacing.** See below.

B. Lead system

1. **Terminal pin.** The male portion of the proximal lead that connects to the pulse generator.

2. **Lead body.** Consists of conductor(s) and insulation. The conducting wire connects the stimulating and sensing electrodes to the terminal pin. The lead insulation is most commonly silicone rubber or a polyurethane material.
3. **Stimulating/sensing electrode(s).** The distal end of the lead that connects via a fixation mechanism to atrial or ventricular myocardium.
4. **Fixation device.** Passive fixation represents an attachment mechanism (e.g., "fins" or "tines") that anchors electrodes to the endocardial trabeculae. Active fixation leads are secured to the endocardium using a "screw-in" mechanism. Over the past decade, active fixation leads have been implanted much more commonly. These types of leads have a lower rate of early dislodgement and yet higher chronic capture thresholds than passive fixation leads.

C. Polarity. This refers to the electrode configuration of the pacing lead or the configuration of the pulse generator. Polarity may be unipolar or bipolar; however, some pacemakers can be programmed to pace in one polarity and sense in another (only if a bipolar lead is present).

1. **Unipolar.** Configuration in which the cathode (negative) is on the lead, usually the lead tip, and the anode (positive) is the pacemaker can. This results in a large sensing "antenna" and produces large pacemaker artifact (spikes) on the electrocardiogram (ECG) due to proximity of the circuit to ECG electrodes.
   a. **Advantages.** Better sensing of premature ventricular contractions (PVCs), low-amplitude signals, and shifted axis.
   b. **Disadvantages.** Oversensing of extraneous signals, especially pectoralis muscle activity (myopotentials), and inadvertent skeletal muscle stimulation may occur. Moreover, large pacemaker artifacts on the ECG may obscure native electrical activity.
2. **Bipolar.** Both electrodes are at the end of the lead—the cathode (negative) at the distal tip and the anode (positive) at the proximal ring. This results in a smaller sensing "antenna" with smaller pacemaker artifact (spikes) on the ECG. Myocardial stimulation occurs as electrons from the cathode travel through the myocardium and back to the anode.
   a. **Advantages.** Less myopotential oversensing and skeletal muscle stimulation, and the smaller pacemaker artifact on the ECG, do not obscure native wave morphology.
   b. **Disadvantages.** More complex lead design is more susceptible to malfunction/failure. Small pacemaker artifact on the ECG may be difficult to see.

D. Lead–heart interface. This is equivalent to the site of energy transfer (pacing) and sensing functions.

III. PACEMAKER CLASSIFICATION. The North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group initially published a "pacemaker code" in 1983. Guidelines were later revised in 2002 and the five-position code remains the accepted nomenclature for pacemaker therapy (see Table 54.1). The first two positions (chamber paced and chamber sensed) are straightforward. The third position, however, is often misunderstood. As outlined in Table 54.1, the third position reflects the device response to a sensed event (labeled "I," "T," or "D"). 'I" (Inhibited)—the device will pulse the given chamber unless it senses an intrinsic event. Thus when programmed DDI, atrioventricular (AV) synchrony will only exist if the atrial chamber is paced. If the atrial activity is intrinsic and the ventricular response depends only on the sensed activity in that chamber, then AV synchrony will not be provided. "T" (Triggered)—this mode is used during device testing where a sensed event results in the device producing a pulse. "D" (Dual)—atrial and ventricular sensing and pacing with dual-chamber devices. When programmed DDD, a sensed atrial beat inhibits atrial pacing and, after a programmed time interval, triggers ventricular pacing. This mode enables tracking of intrinsic atrial activity and corresponding ventricular pacing to allow AV synchrony.

TABLE 54.1 Revised NASPE/BPEG Generic (NBG) Code for Antibradycardia, Adaptive Rate, and Multisite Pacing

Position	I	II	III	IV	V

BPEG, British Pacing and Electrophysiology Group; NASPE, North American Society of Pacing and Electrophysiology. *Pacing Clin Electrophysiol*. 2002;25:260–264.

IV. INDICATIONS FOR PACEMAKER IMPLANTATION. The American College of Cardiology (ACC)/American Heart Association (AHA)/Heart Rhythm Society (HRS) published updated guidelines for indications for pacemaker implantation in device-based therapy of cardiac rhythm abnormalities in 2008 (see Table 54.2).

V. PHYSIOLOGY OF CARDIAC PACING

A. Pulse generator output. This is determined by the output voltage and duration of the stimulating pulse (pulse width). Most implanted cardiac pacemakers use constant-voltage output (as opposed to most temporary cardiac pacemakers, which use constant-current output).

B. Strength–duration relation. There is an exponential relationship between the stimulus amplitude for myocardial stimulation and the pulse width, such that there is a rapidly rising strength–duration curve at pulse widths < 0.25 millisecond and a flatter curve at pulse widths > 1.0 millisecond (see Fig. 54.1).

1. **Rheobase.** The flattened portion of the strength–duration curve indicating the point at which increasing pulse width is no longer associated with a progressive decrease in stimulus amplitude (voltage) required for myocardial stimulation. In general, the rheobase voltage is determined by assessing the threshold stimulus voltage at a pulse width of 2.0 milliseconds.
2. **Chronaxie.** This corresponds to the threshold pulse width at twice the rheobase voltage. The chronaxie pulse duration approximates the point of minimal threshold energy on the strength–duration curve.

C. Safety margins

1. **Voltage.** The voltage output should be programmed to a level that is approximately twice the capture (stimulation) threshold for a 2:1 output safety margin.
2. **Pulse width.** The pulse duration should be programmed to a level approximately three times the pulse width capture threshold for a 3:1 output safety margin. The typical range for pulse width is 0.2 to 1.0 millisecond.

D. Temporal changes in stimulation threshold. Typically, the stimulation threshold rises within 24 hours following implantation of a permanent pacemaker lead. The

TABLE 54.2 Indications for Cardiac Pacing

	Class I	Class II	Class III
SND	1. SND with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms. 2. Symptomatic chronotropic incompetence. 3. Symptomatic sinus bradycardia that results from required drug therapy for medical conditions.	IIa: 1. SND with heart rate < 40 bpm when a clear association between significant symptoms consistent with bradycardia and the actual presence of bradycardia has not been documented. 2. Syncope of unexplained origin when clinically significant abnormalities of sinus node function are discovered or provoked in electrophysiological studies. IIb: In minimally symptomatic patients with chronic heart rate < 40 bpm while awake.	1.Permanent pacemaker implantation is not indicated for SND in asymptomatic patients. 2. Permanent pacemaker implantation is not indicated for SND in patients for whom the symptoms suggestive of bradycardia have been clearly documented to occur in the absence of bradycardia. 3. Permanent pacemaker implantation is not indicated for SND with symptomatic bradycardia due to nonessential drug therapy.
Acquired AV block	1. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level associated with the following conditions: – bradycardia with symptoms (including heart failure) or ventricular arrhythmias presumed to be due to AV block. – arrhythmias and other medical conditions that require drug therapy that results in symptomatic bradycardia. – awake, symptom-free patients in sinus rhythm, with documented periods of asystole ≥3.0 s or any escape rate < 40 bpm, or with an escape rhythm that is below the AV node.	IIa 1. Permanent pacemaker implantation is reasonable for persistent third-degree AV block with an escape rate > 40 bpm in asymptomatic adult patients without cardiomegaly. 2. Permanent pacemaker implantation is reasonable for asymptomatic second-degree AV block at intra- or infra-His levels found at electrophysiological study.	1. First-degree AV block. 2. Asymptomatic type I second-degree AV block at the supra-His (AV node) level or that which is not known to be intra- or infra-Hisian. 3. AV block that is expected to resolve and is unlikely to recur (e.g., drug toxicity, Lyme disease, or transient increases in vagal tone or during hypoxia in sleep apnea syndrome in the absence of symptoms).

TABLE 54.2 Indications for Cardiac Pacing

	Class I	Class II	Class III
	– awake, symptom-free patients with AF and bradycardia with one or more pauses of at least 5 s or longer – after catheter ablation of the AV junction – postoperative AV block that is not expected to resolve after cardiac surgery. – neuromuscular diseases with AV block, such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy, with or without symptoms. Permanent pacemaker implantation is indicated for second-degree AV block with associated symptomatic bradycardia regardless of type or site of block. Permanent pacemaker implantation is indicated for asymptomatic persistent third-degree AV block at any anatomic site with average awake ventricular rates of 40 bpm or faster if cardiomegaly or LV dysfunction is present or if the site of block is below the AV node. Permanent pacemaker implantation is indicated for second- or third-degree AV block during exercise in the absence of myocardial ischemia.	IIb 1. Neuromuscular diseases such as myotonic muscular dystrophy, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy with any degree of AV block (including first-degree AV block), with or without symptoms, because there may be unpredictable progression of AV conduction disease. 2. AV block in the setting of drug use and/or drug toxicity when the block is expected to recur even after the drug is withdrawn.	
Hypertrophic CM	Permanent pacing is indicated for SND or AV block in patients with HCM	IIa: None	1. Permanent pacemaker implantation is not indicated for patients who are asymptomatic or whose symptoms are medically controlled.

(*Continued*)

TABLE 54.2 Indications for Cardiac Pacing (*Continued*)

	Class I	Class II	Class III
		IIb: Permanent pacing may be considered in medically refractory symptomatic patients with HCM and significant resting or provoked LV outflow tract obstruction. *(Level of Evidence: A.)* As for class I indications, when risk factors for SCD are present, consider a DDD ICD	2. Permanent pacemaker implantation is not indicated for symptomatic patients without evidence of LV outflow tract obstruction.
Post MI	1. Permanent ventricular pacing is indicated for persistent second-degree AV block in the His-Purkinje system with alternating bundle branch block or third-degree AV block within or below the His-Purkinje system after ST-segment MI. 2. Transient advanced second- or third-degree infranodal AV block and associated bundle branch block. If the site of block is uncertain, an electrophysiological study may be necessary. 3. Persistent and symptomatic second- or third-degree AV block.	IIa: None IIb: Persistent second- or third-degree AV block at the AV node level, even in the absence of symptoms	1. Transient AV block in the absence of intraventricular conduction defects. 2. Transient AV block in the presence of isolated left anterior fascicular block. 3. New bundle branch block or fascicular block in the absence of AV block. 4. Persistent asymptomatic first-degree AV block in the presence of bundle branch or fascicular block.
Chronic bifascicular and trifascicular block	1. Advanced second-degree AV block or intermittent third-degree AV block. 2. Type II second-degree AV block. 3. Alternating bundle branch block.	IIa: 1. Syncope not demonstrated to be due to AV block when other likely causes have been excluded, specifically VT. 2. Incidental finding at electrophysiological study of a markedly prolonged HV interval (≥100 ms) in asymptomatic patients.	1. Fascicular block without AV block or symptoms. 2. Fascicular block with first-degree AV block without symptoms.

TABLE 54.2 Indications for Cardiac Pacing (*Continued*)

	Class I	Class II	Class III
		3. Incidental finding at electrophysiological study of pacing-induced infra-His block that is not physiological. IIb. 1. Neuromuscular diseases such as myotonic muscular dystrophy, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy with bifascicular block or any fascicular block, with or without symptoms.	
Carotid sinus hypersensitivity (carotid sinus irritability) and neurally mediated syncope	Recurrent syncope caused by spontaneously occurring carotid sinus stimulation and carotid sinus pressure that induces ventricular asystole of more than 3 s.	IIa: Syncope without clear, provocative events and with a hypersensitive cardioinhibitory response of 3 s or longer IIb: Significantly symptomatic neurocardiogenic syncope associated with bradycardia documented spontaneously or at the time of tilt-table testing.	1. Hypersensitive cardioinhibitory response to carotid sinus stimulation without symptoms or with vague symptoms. 2. Situational vasovagal syncope in which avoidance behavior is effective and preferred.
Termination of tachyarrhythmias		Symptomatic recurrent SVT that is reproducibly terminated by pacing when catheter ablation and/or drugs fail to control the arrhythmia or produce intolerable side effects.	Permanent pacing is not indicated in the presence of an accessory pathway that has the capacity for rapid anterograde conduction.

(*Continued*)

TABLE 54.2 Indications for Cardiac Pacing (*Continued*)

	Class I	Class II	Class III
Prevention of tachycardia	Sustained pause-dependent VT, with or without QT prolongation.	IIa: High-risk patients with congenital long QT syndrome IIb: Prevention of symptomatic, drug-refractory, recurrent AF in patients with coexisting SND.	1. Permanent pacing is not indicated for frequent or complex ventricular ectopic activity without sustained VT in the absence of the long QT syndrome. 2. Permanent pacing is not indicated for torsade de pointes VT due to reversible causes. 3. Permanent pacing is not indicated for the prevention of AF in patients without any other indication for pacemaker implantation.
Pacing after cardiac transplantation	Persistent inappropriate or symptomatic bradycardia not expected to resolve and for other class I indications for permanent pacing.	IIa: None IIb: 1. Relative bradycardia is prolonged or recurrent, which limits rehabilitation or discharge after postoperative recovery from cardiac transplantation. 2. Syncope after cardiac transplantation even when bradyarrhythmia has not been documented.	

AF, atrial fibrillation; AV, atrioventricular; CM, cardiomyopathy, ; HCM, hypertrophic cardiomyopathy; ICD, implantable cardioverter–defibrillator; LV, left ventricular; MI, myocardial infarction; SCD, sudden cardiac death; SND, sinus node dysfunction; SVT, sustained ventricular tachycardia; VT, ventricular tachycardia; .
Class I: Conditions for which there is evidence and/or general agreement that pacing is beneficial, useful, and effective.
Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of pacing.
Class IIa: Weight of evidence/opinion is in favor of usefulness/efficacy.
Class IIb: Usefulness/efficacy is less well established by evidence/opinion.
Class III: Conditions for which there is evidence and/or general agreement that pacing is not useful/effective and in some cases may be harmful.

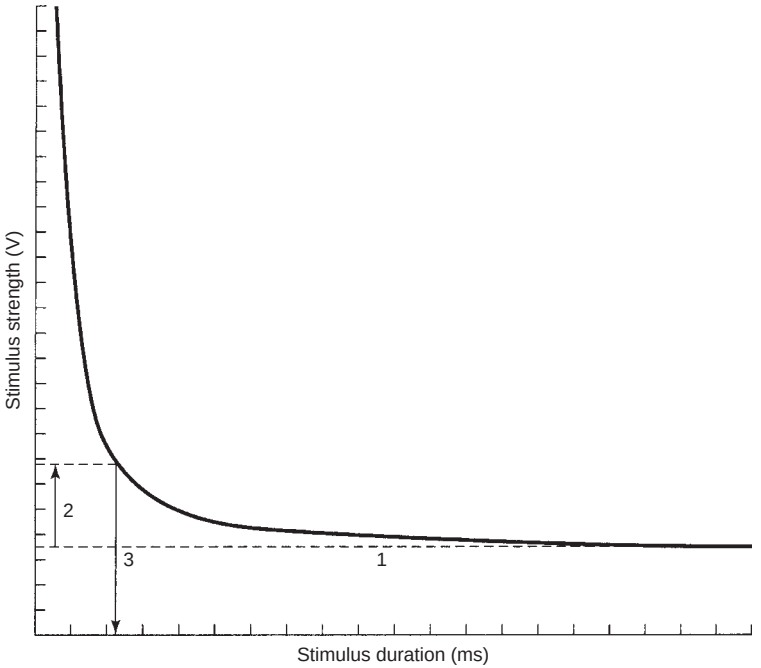

FIGURE 54.1 Strength–duration curve.

threshold peaks at 1 to 2 weeks, then gradually declines and plateaus at approximately 6 weeks at a level less than the acute peak, but greater than that measured at implantation. The absolute value of the temporal changes in stimulation thresholds varies between individuals and also between various types of electrodes.

VI. PACEMAKER TIMING CYCLES AND INTERVALS

A. Timing circuits. A pacemaker can be thought of as a series of timing circuits. An understanding of how these timing circuits interact can facilitate the analysis of pacemaker rhythms. The timing circuit runs until the cycle is completed or until it is reset. Completion of a timing cycle results in the release of a pacing output or the initiation of another timing cycle. Figure 54.2 illustrates the basic timing cycles and intervals for a dual-chamber pacemaker. The basic terms and abbreviations used for the pacemaker timing cycles and refractory periods are defined in the glossary.

B. Base rate behavior

1. Single-chamber pacemakers have a timing circuit that either is inhibited (reset) by a sensed native heartbeat or completes its cycle with a stimulus output. Dual-chamber pacemakers are more complex and incorporate more timing circuits. Figure 54.2 illustrates the timing cycles of a dual-chamber pacemaker in DDD mode. In general, base rate (lower rate) pacing for dual-chamber pacemakers involves two timing circuits.

a. The first timing circuit is the interval from a ventricular sensed or paced event to an atrial-paced event (atrial escape interval or AEI).

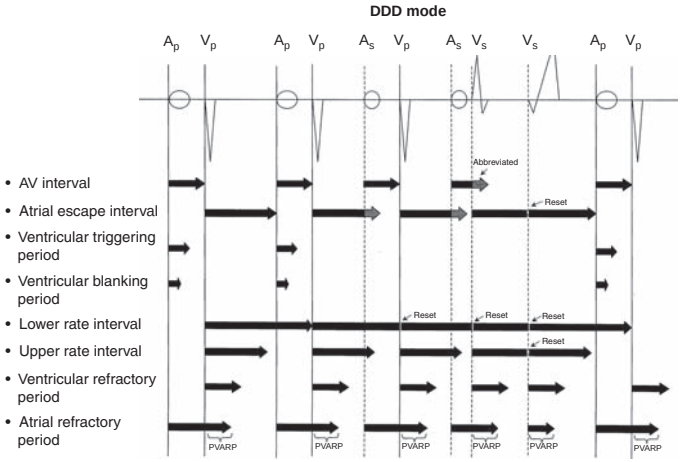

FIGURE 54.2 Timing cycles and intervals for a dual-chamber pacemaker. PVARP, postventricular atrial refractory period.

b. The second timing circuit is the interval from an atrial sensed or paced event to a ventricular paced event (atrioventricular interval, or AVI). An atrial sensed event that occurs before the completion of the AEI results in termination of that interval and initiation of the AVI.

2. The response of a dual-chamber pacemaker to a sensed ventricular signal varies among manufacturers. Some pacemakers use a ventricular-based timing system and others use an atrial-based timing system.
   a. Ventricular-based timing. In this type of pacemaker timing system, the AEI is fixed. A ventricular sensed event during the AEI will reset the timing circuit. A ventricular sensed event during the AVI terminates that interval and initiates the AEI.
   b. Atrial-based timing. In this type of pacemaker timing system, the AA interval is fixed. A ventricular sensed event during the AEI will reset the AA timing circuit and add the programmed AVI. A ventricular sensed event during the AVI will inhibit a ventricular output, but will not alter the AA interval.
3. Interpretation of pacemaker rhythm that has ventricular sensed beats requires knowledge of the type of timing system the pacemaker uses. Both the ventricular-based and atrial-based timing systems should be analyzed by measuring backward from an atrial-paced event. The point of ventricular sensing for a ventricular-based timing system will be found at the point before the atrial-paced event that is equal to the AEI. For an atrial-based timing system, the measurement before the atrial-paced event should be to the point that is equal to the AA interval. Knowledge of these principles allows one to evaluate the ventricular sensing for a given pacemaker. Be aware that some pacemakers have incorporated modifications of these systems that take advantage of features from both timing systems. For example, a pacemaker with an atrial-based timing system may behave as a ventricular-based timing system.
4. **Hysteresis** is a pacing feature that attempts to allow the heart's native conduction system to predominate and therefore modifies base rate behavior. This feature works by using a longer escape interval after a sensed beat than after

a paced beat. For example, the device sets the hysteresis rate at 50 bpm while the basal rate is 60 bpm. Therefore, if the patient's intrinsic rate is > 50 bpm, the device will not pace. However, if the patient's rate falls below 50 bpm, the pacer will pace at 60 bpm. As hysteresis can appear as an unusually long delay on the ECG strip, it can be misinterpreted as failure to pace or as inappropriate sensing.

C. Upper rate behavior

1. As the sinus rate accelerates, the sensed atrial events terminate the AEI and initiate the AVI. The result is P-wave synchronous ventricular pacing (unless the PR interval is shorter than the PV interval, in which case pacing will be fully inhibited).
2. The maximal atrial rate that a dual-chamber pacemaker can sense is determined by the total atrial refractory period (TARP). As defined earlier in this chapter, the TARP is composed of the AVI and the postventricular atrial refractory period (PVARP). The PVARP is an interval during which the atrial channel can see incoming signals, but will not respond to them. However, because signals are seen in PVARP, the pacer can use advanced features to assess whether high atrial rates are occurring. As the sinus rate accelerates, the native atrial intervals become shorter than the TARP, and some atrial events will not be sensed. An abrupt, fixed block occurs as the pacemaker only intermittently senses the P-waves, which may result in symptoms as the rate drops precipitously.
3. Maximal tracking rate interval (MTRI) or upper rate limit is an additional timing circuit designed to avoid abrupt blocks at upper pacing rates. It works in conjunction with the AVI to determine the highest ventricular pacing rate that can be achieved in response to atrial sensed events. A sensed atrial event initiates the AVI and the MTRI.
   a. If the AVI completes its cycle and the MTRI has also completed its cycle, then a ventricular output occurs at the programmed AV interval.
   b. If the AVI completes its cycle and the MTRI has not completed its cycle, then the ventricular output is delayed until the MTRI has timed out. This prolongs the PV interval and allows continued tracking of the atrial rate. However, the longer PV interval also places the ventricular output closer to the following P-wave.
   c. If the sinus rate accelerates to a sufficient rate, the delayed ventricular output may cause the following P-wave to fall within the PVARP and not be sensed. The result is an intermittent "dropped" beat and a pause similar to Wenckebach behavior. However, abrupt block is less likely. More modern pacemakers may incorporate features designed to limit the degree of fixed block at the upper rate limit, such as rate smoothing (adjustment of the AEI as the PV interval changes) and rate-responsive AV delay. However, fixed block at the upper rate limit may still occur, particularly if the device is suboptimally programmed.

VII. RATE-ADAPTIVE PACING.

The primary purpose of rate-adaptive pacing is to emulate the function of the sinus node for patients with chronotropic incompetence or atrial arrhythmias that preclude reliable sensing of native sinoatrial rhythm. This function is expressed with the letter "R" in the fourth position (AAIR, VVIR, DDDR, and so on).

A. Primary components of a rate-adaptive pacemaker system

1. A sensor located in the pacing lead or pacemaker itself detects a physical or physiologic parameter that is directly or indirectly related to metabolic demand.
2. Rate-modulating circuitry within the pacemaker contains an algorithm that translates a change in the sensed parameter to a change in the pacing rate.
3. Algorithm programmability such that a physician can make adjustments to accommodate the heart rate requirements of the individual patient.

TABLE 54.3 Sensors in Rate-Responsive Pacing

Methods	Physiologic parameters	Mechanism	Advantages	Disadvantages
Impedance sensing	Respiratory rate Minute ventilation Stroke volume	Impedance plethysmography	Highly physiologic Highly proportional to metabolic demand	Delayed response Susceptible to electrode motion artifact
Ventricular evoked response	Evoked QT interval (stim-T interval)	Reflects catecholamines	More physiologic	Requires ventricular pacing
Vibration, acceleration, gravitation, motion sensing	Body movement	Piezoelectric element	Rapid response No special lead needed	Nonphysiologic and nonspecific Late plateau response
Special sensors on pacing electrode	Central venous temperature[a] d*P*/d*t*[b] Mixed venous oxygen saturation[b]	Thermistor Piezoelectric element Optical sensor	More physiologic	Complex lead

[a]No longer produced, although still in use in Japan.
[b]Presently available only in clinical trials.

Adapted from Lau, Chu-Pak. The Range of Sensors and Algorithms Used in Rate Adaptive Cardiac Pacing. *PACE*, 1992: 1177–1190.

4. Pacemakers can set the sensor to on or off. Some pacemakers can be put in a passive mode in which they store information in order to predict how the pacer would act if set to rate-responsive behavior.

B. Basic technical categories of pacemaker sensors (see Table 54.3). Motion sensors are the most commonly used due to their simplicity, speed of response, and compatibility with standard unipolar and bipolar pacing leads. Other sensors are more physiologic but may require technically complex pacing leads. Of the physiologic sensors, only the minute ventilation type is widely available. Minute ventilation sensors are prone to interference from electromagnetic sources, coughing, hyperventilation, and arm swinging.

VIII. AUTOMATIC MODE SWITCHING. Automatic mode switching is a programmable response of a dual-chamber pacemaker during an atrial tachyarrhythmia (atrial tachycardia, atrial fibrillation, or atrial flutter) designed to avoid nonphysiologic ventricular pacing due to atrial tracking. Generally, the device switches from a DDD mode to a VVI mode, usually with a gradual reduction of the pacing rate. The device switches back to the DDD mode after the atrial tachyarrhythmia resolves. Mode switch information can also be helpful in documenting atrial arrhythmia burden in order to help dictate medical therapy for arrhythmias.

IX. BASIC PACING MODES. The choice of pacemaker generator and the mode of pacing depend mainly on the underlying rhythm disturbance and whether AV synchrony and rate response are desired (see Table 54.4).

TABLE 54.4 Guidelines for Choice of Pacemaker Generator in Selected Indications for Pacing

	Sinus node dysfunction	AV block	Neurally mediated syncope or carotid sinus hyperreactivity
Single-chamber atrial pacemaker	No suspected abnormality of AV conduction and not at increased risk for future AV block Maintenance of AV synchrony during pacing if desired RR if desired	Not appropriate	Not appropriate (unless AV block systematically excluded)
Single-chamber ventricular pacemaker	Maintenance of AVS during pacing not necessary RR available if desired	Chronic AF or other atrial tachyarrhythmia or maintenance of AVS not necessary RR available if desired	Chronic AF or other atrial tachyarrhythmia RR available if desired
Dual-chamber pacemaker	AVS during pacing desired Suspected abnormality of AV conduction or increased risk of AV block	AVS during pacing desired Atrial pacing desired RR available if desired	Sinus mechanism present RR available if desired
Single-lead, atrial-sensing ventricular pacemaker	Not appropriate	Normal sinus function and no need for atrial pacing Desire to limit the number of pacemaker leads	Not appropriate

AF, atrial fibrillation; AV, atrioventricular; AVS, atrioventricular synchrony; RR, rate response.

A. Ventricular demand pacing (VVI). This remains the most commonly used pacing mode worldwide. Although VVI pacing protects the patient from lethal bradycardias, AV synchrony is not restored or maintained nor does it provide rate responsiveness in the patient with chronotropic incompetence. Because AV synchrony is absent, the rate of pacemaker syndrome is high (up to 83% in randomized trials).

B. AAI (atrial demand pacing). This mode is appropriate for patients with sinus node dysfunction who have intact AV conduction. A sensed atrial event will inhibit atrial pacing, and expiration of a preset AA interval will pace the atrium at a preset rate. Because there will be no ventricular support if AV block should occur, careful testing of AV conduction is necessary at the time of pacemaker implantation (incremental atrial pacing). This mode is infrequently used in the United States.

C. AV sequential pacing

1. **DDI.** There are both atrial and ventricular sensing and pacing, but no atrial tracking can occur. The pacemaker rate is therefore fixed, and this mode is rarely used.

2. **VDD.** In this mode, ventricular stimulation can either be inhibited by a spontaneous ventricular beat or be initiated by an atrially tracked beat, and it can therefore be used in patients with normal sinus function but impaired AV conduction. This modality uses a "floating" sensing electrode on the atrial portion of the ventricular lead, but it is altogether rarely used.
3. **DDD.** This system provides the most physiologic pacing mode. The pacer can be totally inhibited with normal sinus rhythm, can pace the atrium with spontaneous ventricular depolarization, can pace the ventricle in response to a spontaneous P-wave, and can sequentially pace both the atrium and ventricle. This system is most appropriate in patients who have impaired AV conduction with either an intact or dysfunctional sinus node.

X. BIVENTRICULAR PACING.

Because patients with systolic left ventricular (LV) dysfunction and wide QRS complexes have dyssynergic contractility, the use of multisite atrial, right ventricular (RV), and LV pacing strategies has been proposed. For this purpose, an additional pacemaker lead is placed transvenously into the coronary sinus or epicardially during open chest surgery for simultaneous stimulation of the left and right ventricles.

A. Biventricular cardiac resynchronization pacing for heart failure has been accepted as standard therapy for patients with a depressed ejection fraction (EF < 35%), QRS duration > 120 milliseconds, and NYHA class III or IV symptoms despite appropriate medical therapy. Several randomized studies, including MUSTIC, MIRACLE, MIRACLE-ICD, PATH-CHF, and VENTAK-CHF/CONTAK-CD, have demonstrated improved functional status, exercise capacity, and quality of life with biventricular pacing. CARE-HF demonstrated a decrease in the primary end point of death and hospitalization with biventricular pacing (see Chapter 56) in heart failure patients with depressed systolic function, class III/IV symptoms, and wide QRS.

B. Consideration for implantation of a biventricular pacemaker should be given for patients with LV dysfunction who will require a high percentage of ventricular pacing. This recommendation is based on the findings from the DAVID trial where high rates of RV pacing caused ventricular dyssynchrony and more hospitalization for congestive heart failure (CHF) or death.

C. Although the overall rate of clinical improvement with biventricular pacing is high in these trials (about 70% of patients), it is not entirely clear how to identify patients who will respond ahead of time. Multiple echocardiographic and electrocardiographic measures have been investigated to help predict an individual patient's likelihood of clinical response, but so far no single modality has proven entirely reliable.

XI. PACEMAKER IMPLANTATION: PERTINENT ISSUES FOR THE PHYSICIAN

A. Preoperative issues. Several issues must be addressed for the patient scheduled for routine pacemaker implantation.

1. **History and physical examination.** Attention should be given to any findings that may affect the site and approach for pacemaker implantation, such as patient handedness (pacemakers are generally implanted on the contralateral side), history of mastectomy, presence of congenital abnormalities (e.g., anomalous venous drainage), current central venous lines, or tricuspid valve disease or surgery.
2. **Informed consent** (risks, benefits, and alternatives)
3. **Tests**
   - **a.** Posteroanterior and lateral chest radiograph.
   - **b.** Twelve-lead ECG should be obtained.
   - **c.** Blood tests may include serum electrolytes, complete blood count, creatinine, prothrombin/international normalized ratio (INR), and partial thromboplastin times.

4. **Medications**
   a. Most physicians prefer warfarin to be discontinued at least 3 days before the procedure. In some cases, such as primary implants or generator changes, coumadin can be kept close to therapeutic, with INR at approximately 2.0. Consider admission to hospital for intravenous heparin if the risk of discontinuation of anticoagulation is high. Heparin may be discontinued 4 to 6 hours before the procedure.
   b. The dosage of oral hypoglycemics or insulin may have to be adjusted.
5. **Patient preparation**
   a. The patient should have nothing by mouth for at least 6 to 8 hours before the procedure. Intravenous hydration should be initiated upon arrival to the laboratory to prevent hypovolemia, which may make venous cannulation more difficult.
   b. An intravenous catheter is particularly helpful if placed in the arm ipsilateral to the proposed pacemaker site. This allows the ability to perform a venogram if there is difficulty in obtaining venous access during pacemaker implantation.
   c. The patient should be shaved and cleansed (e.g., with povidone iodine) in the area from above the nipple line to the angle of the jaw and from the sternum to the axillary line on the side of the implantation site.
   d. Antibiotic prophylaxis before pacemaker implantation is a controversial issue, and various prospective studies have provided conflicting information. Some centers have advocated antibiotic prophylaxis with an agent active against staphylococci for patients at high risk for endocarditis, such as those with prosthetic valves or complex congenital heart disease, or for redo procedures or for prolonged or potentially contaminating procedures. Other centers use antibiotic prophylaxis routinely (systemically and/or locally).

B. **Postoperative issues**
1. **General recommendations.** Patients are usually admitted for overnight observation on telemetry after pacemaker implantation.
2. **Postoperative testing.** Posteroanterior and lateral chest radiograph should be obtained to document proper position of the pacemaker leads and connection of the terminal pins to the pulse generator. The radiograph should also be examined for evidence of pneumothorax, pericardial effusion, or pleural effusion.
3. **Resuming anticoagulation.** Anticoagulation should not be aggressive in the early post-implantation period due to the risk of pacemaker pocket hematoma, which has been associated with increased risk of complications such as reoperation and infection. Administration of therapeutic doses of unfractionated or low-molecular-weight heparin in the 48 hours following device implantation will increase the risk of hematoma and should generally be avoided. If warfarin was held prior to device implantation, it may be restarted the day prior to device implantation based on the INR.
4. **Pacemaker evaluation**
   a. Evaluation in the pacemaker clinic before discharge includes assessment of pacing and sensing thresholds and lead impedance. The pacemaker is programmed to optimize patient hemodynamics and minimize battery expenditure.
   b. Capture thresholds are expected to rise over the first 2 to 6 weeks after implantation. Therefore, the pacemaker should be programmed with an adequate safety margin to account for these changes.
   c. Rate adaptation for activity-sensing pacemakers may be programmed according to informal (e.g., hallway walking) or formal (e.g., treadmill) exercise testing.
5. **Discharge planning**
   a. **Discharge instruction.** Usually includes patient education regarding the recognition of pacemaker pocket complications, such as signs of infections,

bleeding, or hematoma. The patient is generally advised to avoid heavy lifting or vigorous activity (especially forceful abduction) with the arm ipsilateral to the implant site.

b. The patient should be provided with information regarding his or her pacemaker, including a wallet card identifying the pacemaker and lead(s) manufacturer, model numbers, and serial numbers.

c. The patient may be provided with and instructed in the use of a transtelephonic monitoring system for remote evaluation of the pacemaker.

d. Endocarditis prophylaxis is generally *not* recommended routinely for patients with pacemakers, according to the updated AHA guidelines.

XII. COMMON PACEMAKER PROBLEMS

A. Acute complications of pacemaker implantation

1. Pneumothorax/Hemothorax

a. This complication may be asymptomatic and detected only by chest radiograph. The diagnosis should be considered in a patient with dyspnea and/or pleuritic chest pain after implantation.

b. A small pneumothorax may resolve without intervention. However, the presence of severe symptoms, a pneumothorax > 10%, or an expanding or persistent pneumothorax often necessitates placement of a chest tube.

2. Pacemaker pocket hematoma

a. This is one of the most common complications of pacemaker implantation and is often due to small vessel venous bleeding inside the pacemaker pocket. Bleeding may also arise from arterial vessels or retrograde flow of venous blood along the pacemaker leads into the pocket.

b. Signs and symptoms may include pain, swelling, and sometimes bleeding at the pocket site.

c. Small hematomas may be managed conservatively with pressure dressings, elevation (head of bed at least 45°), and analgesics. The patient should be positioned on his or her side contralateral to the pacemaker site. Large hematomas may compromise the integrity of the incision site and result in dehiscence. The patient may require urgent surgical exploration and hematoma evacuation in the electrophysiology laboratory or operating room.

d. Percutaneous insertion of a needle to drain a hematoma increases the risk of infection and should be avoided.

3. Cardiac or central venous perforation. Perforation may lead to pericardial effusion and cardiac tamponade and should be suspected in the patient with chest pain, pericardial friction rub, or hypotension after pacemaker implantation. A chest radiograph may reveal an enlarged cardiac silhouette or an extracardiac lead tip. A change in the paced ventricular morphology, particularly a right bundle branch pattern, may indicate ventricular lead migration. The hemodynamically unstable patient with tamponade will require urgent pericardiocentesis and drainage of the effusion.

4. Diaphragmatic stimulation. Stimulation of the left diaphragm may occur with a pacing lead at the RV apex, particularly at high pacing outputs. The possibility of cardiac perforation should be considered. Stimulation of the right diaphragm may occur due to stimulation of the right phrenic nerve by a displaced atrial lead. Reduction in the pacemaker output voltage or lead repositioning may be necessary.

5. Local muscular stimulation

a. This may occur with a unipolar pacemaker configuration, particularly if the pulse generator is positioned upside down within the pocket (whereby a node is directly in contact with the pectoralis muscle).

b. A pacing lead fracture may result in leakage of current into the surrounding tissue, resulting in local muscle stimulation.

6. Pacemaker malfunction

a. The pulse generator may be defective or may have been damaged at the time of implantation (e.g., by electrocautery or direct current [DC] defibrillation).

b. Improper fixation of the terminal pins of the pacing leads into the pulse generator (e.g., loose-set screws) may result in complete or intermittent pacemaker malfunction with high impedance measurements.

7. Lead dislodgement or damage

a. Pacing leads may become dislodged soon after implantation before the lead has a chance to become more fixed in place through clotting and fibrosis. Lead dislodgement may be suspected by noncapture, high lead impedance, undersensing, or oversensing on telemetry or ECG and may be confirmed by chest radiography or formal pacemaker testing.

b. The lead may be damaged at the time of implantation by forceful handling or excessively tight retention sutures.

c. Interrogation of a device with a damaged lead may reveal changes in impedance. A break in the insulation of the lead results in low impedance. A contained fracture of the lead conductor, poor terminal pin to device connection, or lead dislodgement all result in high impedance.

B. Chronic complications of pacemaker implantation

1. Pacemaker system infection

a. The reported incidence of pacemaker infection is 1.9 per 1,000 device-years based on a large cohort study spanning 30 years (1). As noted earlier, the number of pacemakers implanted annually continues to increase, and yet the rate of device-related infections is increasing at a disproportionately higher rate. Recognition of these infections and appropriate treatment is critical for health-care providers managing patients with cardiac implantable devices. The infection may involve only the pacemaker pocket or the entire system, with subsequent life-threatening sepsis. There is a higher incidence with repeat operations (e.g., pulse generator replacement). Causative organisms tend to be skin flora such as *Staphylococcus* species.

b. Treatment should include intravenous antibiotics; however, antibiotic therapy rarely eradicates the infection unless the pacemaker system is removed. In the largest study to date (1), mortality rates for device-related endocarditis range from 31% to 66% without device removal. Mortality improves to 18% or less with a combined approach of medical therapy and complete device removal.

c. The timing of system removal depends on the clinical status of the patient; however, prolonged delays should be avoided.

2. Intravascular thrombosis or obstruction

a. Vascular complications are common with device therapy. They range from asymptomatic venous occlusion to extremity edema. Mortality from vascular complications is rare. Initial treatments may include heat and upper-extremity elevation. Symptomatic thrombosis of the subclavian or axillary veins may require anticoagulation or systemic thrombolytic therapy. It is recommended that documented deep venous thrombosis be treated with anticoagulation with warfarin for at least 6 months, unless contraindicated.

b. Superior vena cava stenosis or occlusion may require percutaneous balloon dilatation or surgical consultation for consideration of repair.

3. Twiddler's syndrome. A condition in which the pacemaker is turned, usually unintentionally, upside down within the pacemaker pocket. The leads may become twisted, resulting in excessive traction on the leads and dislodgement.

XIII. PACEMAKER SYSTEM MALFUNCTION

A. In assessing the patient with suspected pacemaker malfunction, it is important to interpret the ECG carefully. Ideally, intracardiac tracings obtained by pacemaker interrogation should be interpreted. Pacing artifacts or spikes are high-frequency signals and are often filtered out by newer digital surface ECG machines. Furthermore, pacing artifacts from bipolar leads are smaller and more difficult to see than artifacts from unipolar leads. It may be necessary to record multiple leads or use an older analogue recorder to clearly visualize the pacing artifact. Pseudomalfunction occurs when recording and digital artifacts are misinterpreted. Approaching the paced patient's ECG systematically will help to determine the appropriateness of pacing.

B. General evaluation for possible pacemaker malfunction

1. If a recent pacemaker interrogation is available, review the programmed parameters for the pacemaker, particularly the mode, base rate, upper rate limit, intervals, and the presence of other features such as automatic mode switching, hysteresis, rate-adaptive features, or managed ventricular pacing.
2. Obtain a 12-lead ECG and evaluate the following:
   - **(a)** Determine whether pacing stimulus artifacts are present and whether the appropriate chamber is captured.
   - **(b)** If no pacing stimulus artifact can be seen, native depolarization should be adequate.
   - **(c)** Evaluate whether native beats are appropriately sensed in relation to paced complexes.
   - **(d)** Evaluate the timing cycles of a dual-chamber pacemaker by measuring backward from an atrially paced event, as described in Section **VI.B.2**.

C. Patients with pacemaker system malfunction generally demonstrate absence of a pacing stimulus artifact, failure to capture, or failure to sense.

1. **Failure of pacemaker stimulus output.** A differential diagnosis of the more common causes of pauses during a paced rhythm is listed later in this chapter. Application of a magnet over the pacemaker should result in asynchronous pacing. If the pauses resolve when the magnet is applied, then the diagnosis of oversensing is most likely. If the pauses do not resolve, then one of the other causes should be considered.
   - **a. Pulse generator failure.** The pulse generator may be at the end of life (EOL), which may easily be detected with a pacemaker check.
   - **b. Lead failure.** This can be due to loose-set screw or terminal pin disconnection, lead conductor failure, or lead insulation failure. Suspicion of lead malfunction should prompt the clinician to obtain a chest radiograph. This may reveal the terminal pin not situated properly within the header of the pulse generator or it may demonstrate a defect in the lead insulation or conductor coil. A significant increase in the lead impedance suggests lead conductor failure, and a significant decrease in the lead impedance suggests lead insulation failure.
   - **c. Oversensing.** EMI, myopotentials, cross talk, or T-wave oversensing can lead to falsely interpreted signals.
   - **d. Pseudomalfunction.** Pacemaker malfunction can be mistakenly diagnosed if the small spikes from a bipolar system are not appreciated on the surface ECG. Malfunction can also be diagnosed mistakenly if attention is not paid to additional features that allow the heart rate to fall below or above the set base rate. It is important to remember additional features such as hysteresis, sleep settings, rate-adaptive behaviors, or automatic mode switch, each of which can be mistaken for pacemaker malfunction.
2. **Failure to capture**
   - **a. Elevated capture threshold.** Electrolyte disturbance (e.g., hyperkalemia and acidemia), antiarrhythmic drugs (particularly class Ic agents such as

flecainide), and myocardial fibrosis (e.g., cardiomyopathy and myocardial infarction [MI]) can increase the capture threshold.

b. Lead malfunction

(1) Lead fracture.

(2) Lead dislodgement or perforation may result in a change in the paced morphology, especially a change from left to right bundle branch morphology.

c. Exit block. Exit block is defined as failure of the pacing output at the distal electrode to stimulate adjacent myocardium. This is often caused by the inflammatory reaction that occurs at the pacemaker lead tip at the time of implantation. It occurs in approximately 5% of cases and may be managed with systemic steroids. Most pacing leads have steroid-eluting electrodes designed to minimize the degree of inflammation at the electrode tip and decrease the incidence of exit block.

d. Latency. Defined as the delay between the delivery of an output pulse and the onset of electrical systole, such as occurs with severe electrolyte disturbances.

e. Pseudomalfunction. Artifact with small spikes on the surface ECG, such as occurs when the patient's refractory periods interfere with pacer function.

3. Failure to sense

a. Lead dislodgement is usually accompanied by failure to capture (see discussion in Section **XIII.C.2**)

b. Lead insulation failure (see discussion in Section **XIII.C.1**)

c. Inadequate endocardial signal

d. Change in electrogram. Transient changes may occur due to electrolyte or acid–base disturbance, and permanent changes may occur due to MI or cardiomyopathy

e. Ectopic beats

f. Pulse generator failure (sensing circuits)

g. Functional undersensing. Defined as undersensing that occurs due to normal pacemaker function, such as refractory periods, blanking periods, or safety pacing.

D. Other pacemaker malfunctions

1. Pacemaker syndrome. Pacemaker syndrome is defined as the signs and symptoms that occur in the pacemaker patient because of inadequate timing of atrial and ventricular contractions. Pacemaker syndrome is commonly caused by retrograde ventriculoatrial (VA) conduction, which causes atrial contraction against closed mitral and tricuspid valves. Pacemaker syndrome may also occur during an exercise-induced atrial arrhythmia due to loss of AV synchrony when a device with an automatic mode-switching feature converts to VVI pacing.

2. Pacemaker-mediated tachycardia (PMT). This is defined as a paced tachycardia that is sustained by the continued active participation of the pacemaker in the rhythm. At first glance, the resultant wide-complex (paced) tachycardia may appear to be ventricular tachycardia, especially for pacemakers with bipolar leads where the pacing artifact may be difficult to discern on ECG.

a. One form of PMT is the rapid ventricular pacing that occurs as a dual-chamber pacemaker attempts to track the rapid atrial rate during an atrial tachyarrhythmic episode.

b. Another form of PMT occurs when there is oversensing in the atrial channel, such as myopotentials.

c. Endless-loop tachycardia (ELT). PMT in which a repetitive sequence of sensing of retrograde atrial activity results in triggering of a ventricular paced beat at the end of the MTRI. ELT requires a trigger for initiation, which may be any event that results in AV dissociation and allows retrograde VA

conduction to occur after a native or paced ventricular beat. The trigger may be a PVC, atrial undersensing, atrial oversensing, or atrial noncapture. ELT is sustained until there is VA block. Application of a magnet over the pacemaker will terminate ELT. The most reliable way to prevent ELT is to program the PVARP to a value that exceeds the VA conduction interval. Some of the more modern pacemakers have PMT or ELT recognition and termination algorithms designed to prevent and/or terminate PMT and ELT.

XIV. COMMON ISSUES FOR THE PATIENT WITH A PACEMAKER

A. Perioperative patient

1. **Preoperative assessment.** Review of pertinent history and a physical examination should be performed. The patient should undergo a pacemaker evaluation to assess the programmed parameters, pacing and sensing thresholds, and lead impedance.
2. The degree of pacemaker dependence should be determined. A patient who is pacemaker-dependent should have temporary pacing equipment readily available.
3. If the operative field is in the area near the pacemaker, the rate response feature of the pacemaker should be deactivated to avoid inappropriate rapid pacing due to vibrations or pressure transmitted to the pulse generator.
4. Electrocautery may result in temporary inhibition of pacemaker output due to oversensing of the EMI. Electrocautery should be used sparingly and in short bursts, and the cautery electrode should be placed at a distance from the pacemaker site.
5. Postoperatively, the pacemaker should be reevaluated for any sign of malfunction, the presence of a reset mode, and any change in lead threshold or impedance values. A chest radiograph should be obtained after cardiac surgery to evaluate for lead damage or dislodgement.

B. EMI in the hospital environment

1. **Magnetic resonance imaging (MRI).** The magnetic field generated by the electromagnet and the radiofrequency signal produced to modulate the magnetic field for MRI may cause torque forces or malfunction of cardiac pacemakers. More modern pacemakers contain fewer ferromagnetic components than previous pacemakers, so that torque forces are less common. The magnetic forces may close the pacemaker reed switch and result in asynchronous pacing. The radiofrequency signal may result in inhibition of pacing, rapid pacing, or reversion to reset mode. Unipolar pacemakers are more susceptible to interference from MRI. While a small number of centers have developed specific scanning protocols for patients with cardiac implantable electronic devices (CIEDs), in general, MRI should be avoided in most pacemaker patients unless absolutely necessary.

   Recently, MRI conditional pacemaker systems have emerged. Specifically, the RevoMRI SureScan System has been evaluated in a clinical trial (EnRhythm MRI SureScan Pacing System Study) and is now widely available for use in clinical practice. Of the 211 enrolled patients who underwent an MRI 9 to 12 weeks after receiving the device, no MRI-related complications were reported. As new applications for MRI continue to emerge in clinical practice, recent estimates suggest that as many as 50% to 75% of patients with CIED will have an indication for MRI during their lifetime. MRI conditional technology will undoubtedly continue to evolve and is likely to become standard in new pacemaker systems from all major manufacturers.
2. **Extracorporeal shock-wave lithotripsy (ESWL)**
   a. ESWL is a treatment for renal calculi that involves the production of focused hydraulic shock waves from an underwater spark gap. Interference or damage to a pacemaker may occur due to the spark gap or the shock

waves. Activity-based rate adaptation pacemakers with piezoelectric crystals may be damaged by the shock waves, and the shock waves may cause oversensing and subsequent nonphysiologic rapid pacing rates. Such pacemakers should be reprogrammed with the rate-adaptive feature deactivated before the procedure. If the pacemaker with a piezoelectric crystal is located in the abdomen, then ESWL should not be performed.

b. The shock waves may be misinterpreted as atrial activity; therefore, dual-chamber pacemakers should be programmed to VVI mode to avoid rapid ventricular pacing.

c. A patient with a pacemaker may undergo ESWL; however, the pulse generator should be as far as possible from the focal point of the lithotripsy shock waves, and a cardiologist who is experienced in pacemaker management should be available nearby during the procedure.

3. Radiation therapy

a. Diagnostic radiation does not interfere with cardiac pacemakers. Therapeutic radiation therapy to the thorax such as that used for breast or lung malignancies may result in interference and/or cumulative damage. The damage to the integrated circuitry of the pacemaker results from leakage currents between the insulated parts. This damage is directly related to the cumulative radiation dose.

b. The pacemaker should be assessed before and after a treatment session. ECG monitoring is recommended for patients who are pacemaker-dependent. The pulse generator should be shielded from the ionizing radiation or moved to another site if necessary.

4. Cardiac monitors. Cardiac monitors that inject current into the patient's body in order to measure minute ventilation may interfere with pacemakers that use minute ventilation for rate adaptation.

5. Transcutaneous electric nerve stimulation is considered safe for patients with bipolar pacemakers. Patients with unipolar pacemakers may require a reduction in sensitivity.

6. Dental equipment. Some types of dental equipment may cause pacemaker inhibition, particularly for unipolar pacemakers. Vibrations may increase the pacing rate of activity-sensing rate-adaptive pacemakers.

7. Cardioversion/defibrillation. The shock from a DC cardioversion or defibrillation may cause damage to the pulse generator or result in the device being reset. If DC cardioversion or defibrillation is necessary, the patch electrodes should be positioned as far as possible from the pulse generator. A pacemaker evaluation should be performed after the procedure.

8. Electroconvulsive therapy generally does not interfere with pacemaker function. The patient should have a pacemaker evaluation before and after each session. ECG monitoring during the session is prudent. Seizure activity during the procedure may produce myopotential inhibition of unipolar pacemakers.

9. Diathermy may result in pacemaker interference or damage if applied to the region near the pulse generator.

10. Electrocautery (discussed in Section **XIV.A.4**)

C. Environmental EMI

1. Cellular telephones. These devices are generally safe. Older models were reported to interfere with cardiac pacemakers while transmitting or receiving calls. A pacemaker patient should not carry a cellular telephone near the pacemaker site (i.e., shirt pocket) and should avoid holding the telephone to the ipsilateral ear during use.

2. Electronic article surveillance (EAS) is a type of antitheft system consisting of a gate that produces an electromagnetic field through which individuals must walk. The field may result in pacemaker interference, primarily inhibition of

pacemaker output. Patients with unipolar dual-chamber pacemakers are particularly susceptible to interference from EAS systems.

3. **Industrial electrical equipment.** This includes devices, such as arc welders, that may generate strong electrical fields. The strength of the electrical field varies among various types of equipment and if sufficiently strong may interfere with unipolar pacemakers. Patients may require individual environmental testing to ensure safety.
4. **Microwave ovens.** Due to better sealing of microwave ovens and improved shielding of pulse generators, interference with pacemakers by microwave ovens is no longer considered a significant problem.
5. **Metal detectors.** Although the metal detectors in public places such as airports may raise an alarm due to detection of a pacemaker, there is generally no significant interference with pacemaker function. Patients should avoid lingering around these devices and pass through them at a normal speed.
6. **High-voltage power lines and electrical substations.** These areas may cause inhibition or asynchronous pacing in unipolar pacemakers if the patient is quite close to the electrical field. At usual public distances from such areas, there should be no pacemaker interference.

D. Pacemaker response to EMI

1. **Pacing inhibition.** For obvious reasons, this may be catastrophic. The majority of pacemakers used today contain protective algorithms that make prolonged inhibition uncommon.
2. **Rapid pacing.** Oversensing of EMI by the atrial channel in a device set to DDD can cause the pacer to trigger ventricular pacing at or near the upper tracking limit. This response is usually well tolerated, but in certain individuals when sustained it may cause palpitations, hypotension, or angina. Rapid pacing may also occur via activation of minute ventilation sensors.
3. **Reversion to asynchronous pacing.** Most pacers have algorithms that protect against prolonged inhibition from noise. Algorithms are based upon the principle that detected rapid frequency signals are unlikely to represent myocardial activation. The pacemaker is programmed to have a noise sampling window during the ventricular refractory period. In most devices, repetitive signaling detected in the noise sampling window reverts the device to asynchronous pacing. Asynchronous pacing is generally safe, but it is not without the risks of losing AV synchrony. Also, pacing may rarely occur during the ventricular vulnerable period and may initiate ventricular arrhythmias.

XV. CARDIAC PACING: CLINICAL TRIALS

A. Conventional pacing trials

1. Numerous clinical trials, mostly small and nonrandomized, have been performed with regard to exercise capacity and quality of life for various pacemaker modes, chamber(s) paced, rate-adaptive pacing, and types of sensors.
2. Clinical trials have firmly established the superiority of rate-adaptive (VVIR) over fixed-rate ventricular pacing (VVI) with regard to quality of life and exercise performance.
3. Numerous clinical trials have been undertaken to prove the benefit of dual-chamber/atrial-based pacing in patients undergoing postoperative permanent pacemaker implantation for sinus node dysfunction or high-degree AV block.
4. There are conflicting data regarding the benefit of dual-chamber pacing over rate-adaptive ventricular pacing. Early nonrandomized trials demonstrated mortality benefit with DDD pacing over VVI in patients with complete heart block. However, in randomized prospective trials, atrial pacing has not been shown to decrease rates of death or heart failure in patients treated for sinus node

dysfunction and high-degree AV block. However, there are several randomized trials demonstrating that atrial-based pacing does, in fact, lead to a reduction in both atrial fibrillation and stroke. However, this benefit may be limited to patients with sinus node dysfunction. The one clear benefit that dual-chamber/atrial-based pacing provides is the avoidance of pacemaker syndrome, which can be seen in up to 10% of patients with VVI pacing.

5. The following paragraphs summarize some of the larger-scale, randomized studies of ventricular- versus atrial-based cardiac pacing modes.
   a. **Pacemaker Selection in the Elderly (PASE) trial.** A single-blind, randomized, controlled trial of ventricular pacing versus dual-chamber pacing in 407 patients older than 65 years. The primary end point was quality of life with up to 30 months follow-up. Quality of life improved with pacemaker implantation. Patients with sinus node dysfunction, but not AV block, had significantly better quality of life with dual-chamber pacing than with ventricular pacing (2).
   b. **Canadian Trial of Physiologic Pacing (CTOPP).** In this trial, 1,474 patients were assigned to ventricular pacing and 1,094 patients to physiologic pacing. During a mean follow-up period of 3 years, there was no significant effect on the risk of death, stroke, or hospitalization for CHF according to the type of pacemaker used. However, the annual rate of atrial fibrillation was significantly lower in the atrial pacing group, although there was a 2-year delay before this beneficial effect emerged. There was a 50% reduction in perioperative complications with the implant of ventricular pacing systems, but in the ventricular pacing group there was a 5% incidence of pacemaker syndrome that required upgrade to a dual-chamber device (3).
   c. **Mode Selection Trial in Sinus Node Dysfunction (MOST).** A randomized trial that attempted to compare dual-chamber with single-chamber ventricular pacing in 2,010 patients with sinus node dysfunction. There was no advantage for dual-chamber pacing over single-chamber ventricular pacing in terms of the trial's primary end point: death from any cause or nonfatal stroke over 33.1 months of follow-up. However, some advantages were seen with the dual-chamber modality in secondary end points, including reductions in atrial fibrillation and symptoms of heart failure and improvement in quality of life (4). There was no difference in heart failure admission rates between the two groups.
   d. **Pacemaker Atrial Tachycardia (Pac-A-Tach) trial.** This was a mode randomization study in 198 patients (median age 72 years), all of whom received dual-chamber rate-adaptive pacemakers programmed to either VVIR or DDDR pacing. Intention-to-treat analysis showed no significant difference in atrial tachyarrhythmia recurrence rates at 1 year (VVIR 43%; DDDR 48%; $p = 0.09$) (5).
   e. **UK Pacing and Cardiovascular Events (UK PACE) trial.** This was a trial comparing VVI(R) and DDD pacing in 2,021 elderly patients (mean age 80 years) with high-grade AV block. Patients were randomized to DDD (50%), VVI (25%), and VVIR (25%). No difference was detected in rates of stroke, atrial fibrillation, or heart failure hospitalizations (6).
   f. **Meta-analysis of trials comparing atrial- and ventricular-based pacing.** Healey et al. (5) in 2006 completed a large meta-analysis of all randomized controlled trials comparing ventricular- and atrial-based pacing modes. A total of 35,000 patient-years of follow-up were reviewed (7). There was no significant reduction in mortality or heart failure with atrial-based pacing. However, there was a significant reduction in atrial fibrillation (hazard ratio 0.80, 95% confidence interval [CI] 0.77 to 0.89) and a borderline reduction in stroke (hazard ratio 0.81, 95% CI 0.67 to 0.99).

6. The practice of RV apical pacing as the preferred method remains controversial. It provides a reliable and stable position for long-term ventricular pacing. However, RV pacing creates ventricular desynchronization and leads to several adverse effects, including LV systolic and diastolic dysfunction. Retrospective and prospective analysis has linked increased numbers of RV paced beats with increased incidence of atrial fibrillation and heart failure. Current forms of pacemaker technology that minimize RV pacing are preferred to older pacemaker technologies. The following are landmark trials that have associated RV pacing with deleterious outcomes.
   a. **DAVID.** The DAVID trial was the first study of ventricular pacing strategies in implantable cardioverter–defibrillator patients. The trial hypothesized that dual-chamber pacing would result in a lower rate of heart failure in these patients with EF < 40% (8). At 1 year, rates of death and first hospitalization for heart failure were significantly increased in the dual-chamber group. The authors noted an increased rate of RV apex pacing in the DDD-70 group (60%) versus the VVI-40 group (3%). The authors concluded that the greater exposure to the deleterious effects of RV pacing in the DDD group led to worse outcomes.
   b. **SAVE PACe.** This trial examined whether the application of newer technologies to limit frequency of ventricular pacing could lead to a decrease in atrial fibrillation in patients with dual-chamber pacemakers. Patients with sinus node disease, intact AV conduction, and a normal QRS interval were randomly assigned to receive conventional dual-chamber pacing or dual-chamber minimal ventricular pacing with the use of features to promote AV conduction and reduce ventricular dyssynchrony (9). Persistent atrial fibrillation was found to occur less frequently in the dual-chamber minimal ventricular pacing group (hazard ratio 0.60, 95% CI 0.41 to 0.88) than in the conventional dual-chamber group
   c. **Recommendations.** The most recent recommendations for cardiac pacing and resynchronization released by the AHA/ACC/HRS in 2008 specifically address the implications of apical versus RV outflow tract/septal pacing. The recommendations mention that small trials have demonstrated septal pacing preserved LV function over the mid- to long term and that His bundle pacing also appears to be beneficial. However, the guidelines note that it is too early to propose a recommendation concerning the optimal location of the RV pacing lead.

XVI. EVOLVING INDICATIONS FOR PACEMAKER THERAPY

A. Hypertrophic cardiomyopathy

1. **Presumed mechanism of benefit.** The idea of RV pacing to treat hypertrophic cardiomyopathy is based on the effective increase in left ventricular outflow tract (LVOT) diameter caused by altered septal activation.
2. **Recommendations.** Pacing is a class IIb recommendation in the 2008 ACC/AHA/HRS guidelines and is reserved for symptomatic drug-refractory patients with significant LVOT gradients who have contraindications for septal ablation or myectomy (see Table 54.2).

B. Long QT syndrome

1. **Presumed mechanism of benefit.** In patients with long QT syndrome, life-threatening episodes of polymorphic ventricular tachycardia and Torsades are typically preceded by pauses or severe bradycardia. By preventing these episodes, pacing may decrease the likelihood of events.
2. **Recommendations.** The 2008 ACC/AHA/HRS guidelines state that permanent pacing is reasonable for high-risk patients with congenital long QT syndrome.

XVII. FUTURE DIRECTIONS

A. Sensor technology. Advances in physiologic sensors and rate adaptation algorithms include the following.

1. **Multiple sensors for more physiologic pacing.** For example, a desirable sensor combination is an activity sensor, which typically has a more rapid response, and another sensor such as minute ventilation, which typically has a more delayed but workload-proportional response.
2. **Sensor blending** refers to the relative contribution of each sensor during each phase of activity and may be programmable.
3. **Sensor "cross-checking"** is done to determine if an increase in the intrinsic atrial rate is appropriate. If the sensor does not confirm activity while the pacemaker senses an increased atrial rate, the pacemaker will use the sensor to dictate the appropriate heart rate. Also, pacemakers with multiple sensors are able to detect intersensor disagreement and thereby avoid inappropriately rapid pacing due to a false-positive response of one sensor.

XVIII. GLOSSARY

A. Cardiac pacing: basic terminology

1. **"60,000 rule".** Converts rate (bpm) to interval (milliseconds) and vice versa, as there are 60,000 milliseconds in 1 minute. Note the formula: 60,000/interval (milliseconds) = rate (bpm).
2. **Anode.** Refers to the positive pole. The anode of a unipolar pacing system is the pulse generator case. The anode of a bipolar pacing system is the proximal ring electrode of the pacing lead.
3. **Capture.** The effective cardiac depolarization resulting from a pacing stimulus.
4. **Cardiac stimulation threshold (mA).** The minimal electrical energy required to consistently depolarize cardiac tissue through a given electrode. This threshold changes with time after implantation (acute, subacute, and chronic).
5. **Cathode.** Refers to the negative pole. The cathode of a unipolar pacing system is the electrode at the distal portion of the pacing lead. The cathode of a bipolar pacing system is the distal tip electrode of the pacing lead.
6. **Cross talk.** In dual-chamber pacing systems, the inappropriate detection (sensing) of an event or signal in one chamber by the sense amplifier of the other chamber (usually inhibition of a ventricular output pulse due to ventricular channel detection of an atrial output pulse).
7. **Current** (***I***). The rate of transfer or the flow of electricity, measured in milliamperes (mA).
8. **Elective replacement interval (ERI), also known as elective replacement time (ERT) or recommended replacement time.** Terms indicating the pulse generator has reached a point in its service life where system failure will likely occur within 3 to 6 months. The ERI indicator for a pacemaker varies between models and manufacturers, but is usually indicated by a change in pacing rate, mode, or function. Pacemaker manufacturers generally recommend pulse generator replacement when the ERI is identified. ERI/ERT indicators for various pacemaker models are published in a handbook that should be available in the pacemaker clinic.
9. **External EMI.** Electrical signals from noncardiac or nonphysiologic sources that may affect pacemaker function. Sources of EMI are discussed below.
10. **End of life.** Term indicating the depletion of battery power for the pulse generator. The EOL indicator for a pacemaker varies between models and manufacturers, but is usually indicated by a decrease in the magnet-related pacing rate to a certain percentage of the beginning-of-life rate. There may also be a change in pacemaker mode (e.g., from DDD to VVI). Telemetry of the

cell impedance of the pulse generator also provides information regarding the status of battery power for those pacemakers with such a feature. Pacemaker manufacturers generally recommend urgent pulse generator replacement if EOL of a device is identified. EOL indicators for various pacemaker models are published in a handbook that should be available in the pacemaker clinic.

11. **Fusion.** Results when the pacemaker output occurs at the same time as an intrinsic event, and both contribute to cardiac depolarization. The morphology of the fused beat has characteristics of both the paced and intrinsic events.
12. **Impedance** (***Z***). Total resistance to the flow of current through a conductor. For pacemaker systems, this includes resistance produced by electronic components and body tissues. Temporal changes in pacing impedance usually include a decreasing impedance over the first 1 to 2 weeks following implantation, then increasing impedance to a level that is somewhat higher than the impedance at the time of implantation. Serial measurements of pacing impedance may be useful for assessing lead integrity, as discussed later in this chapter.
13. **Magnet mode.** The response of a pacemaker when a magnetic field of sufficient strength is applied and closes the pulse generator's reed switch. The pulse generator paces at a predetermined rate and mode, which vary among pacemaker models and manufacturers. Generally, the mode is asynchronous pacing. Magnet mode can be used to assess pacemaker function and battery status (see discussion on ERI in Section **XVIII.A.8** and on EOL in Section **XVIII.A.10**).
14. **Noncapture.** The absence of cardiac depolarization following a pacing stimulus.
15. **Ohm's law.** $V = I \times R$ (*voltage* = *current* × *resistance*).
16. **Output.** The output of a pacemaker is determined by the voltage and pulse width.
17. **Oversensing.** The sensing of inappropriate cardiac or extracardiac signals and responding to them as if they were appropriate native sensed events. "Oversensing results in underpacing."
18. **Pacemaker-mediated tachycardia.** Sudden onset of a sustained ventricular paced rhythm at the maximum tracking rate of the pacemaker. PMT is sustained by continued active participation of the pacemaker in the tachycardia circuit. PMT is discussed in more detail in Section **XIII.D.2**.
19. **Pacing interval (milliseconds).** The interval between two consecutive paced events.
20. **Pseudofusion.** Results when an intrinsic event occurs before the pacemaker output is delivered. When this happens, the pacemaker output does not contribute to cardiac depolarization. The morphology of the pseudofusion beat resembles the intrinsic event.
21. **Pseudo-pseudofusion.** Results when a PVC that resembles the ventricular paced complex follows an atrial output spike.
22. **Pulse width.** The measurement in milliseconds of the pacemaker output spike (also known as pulse duration).
23. **Reed switch.** A switch within the pulse generator that closes when a magnetic field of sufficient strength is applied to it (such as a ring or donut magnet, or a programming head). The pacemaker will convert to magnet mode.
24. **Resistance** (***R***). The opposition to the flow of electrical current through a material, measured in ohms.
25. **Sensing.** The ability of a pacemaker to recognize native cardiac signals. Refers to the amplitude of the signal (mV) required for the pacemaker to detect the signal. Higher numbers reflect less sensitivity; lower numbers reflect more sensitivity.
26. **Undersensing.** The failure to recognize and respond appropriately to cardiac signals. "Undersensing results in overpacing."
27. **Voltage** (***V***). The difference in potential energy between two points, measured in mV.

B. Cardiac pacing: timing cycles and refractory periods

1. A = atrial-paced event.
2. Absolute refractory period: The period following a sensed or paced event during which the sense amplifier is unresponsive to incoming signals.
3. AEI = atrial escape interval: For atrial single-chamber pacing systems, the period from a sensed atrial event to the next atrial-paced event. For dual-chamber pacing systems, the period initiated by a ventricular sensed or paced event and ending with the next atrial-paced event.
4. ARP = atrial refractory period, which is the atrial timing cycle during which the atrial sense amplifier is unresponsive to incoming signals. For single-chamber atrial pacing modes, the atrial refractory period is initiated by an atrial sensed or paced event. For dual-chamber pacing modes, the AV interval and the PVARP determine the TARP. TARP = AVI + PVARP.
5. AV = atrioventricular sequential pacing.
6. AVI = atrioventricular pacing interval (also known as AV delay): In dual-chamber pacing, the period between an atrial sensed or paced event and a ventricular paced event (usually programmable).
7. Blanking period: An interval (usually 12 to 125 milliseconds) initiated by an output pulse during which the sense amplifier is temporarily disabled. In dual-chamber pacing, the blanking period is designed to prevent the inappropriate detection of signals from the other chamber (cross talk). For example, an atrial sensed or paced event initiates a ventricular blanking period during which the ventricular sense amplifier is temporarily disabled.
8. CDW = cross talk detection window: In dual-chamber pacing, a timing cycle (usually 51 to 150 milliseconds) immediately following the ventricular blanking period during which a ventricular sensed event is considered to be cross talk but results in a triggered ventricular output at the end of an abbreviated AV interval (safety pacing).
9. LRL = lower rate limit (also known as base rate or minimum rate): The rate at which the pacemaker paces in the absence of sensed intrinsic events (generally programmable in most pacemakers).
10. MSR = maximal sensor rate: A programmable value in rate-adaptive pacemaker systems that designates the highest pacing rate that can be achieved in response to a sensor input. The MSR may be programmed independently of the MTR.
11. MTR = maximal tracking rate (also known as upper rate limit, URL): A programmable value for dual-chamber pacemaker sensing and tracking modes that designates the highest ventricular pacing rate that can be achieved in response to atrial sensed events with 1:1 AV synchrony at the programmed AV delay.
12. P = native atrial depolarization.
13. R = native ventricular depolarization.
14. Relative refractory period: A "noise sampling" period following the absolute refractory period during which some incoming signals (generally those signals in the frequency range of interference) are monitored by the sense amplifier. Sensed signals during this period may result in the initiation of a new refractory period but do not reset the timing circuit.
15. RRAVD = rate-responsive atrioventricular delay. A programmable feature of some dual-chamber pacing systems that progressively shortens the PV or AV interval as the sinus or sensor-driven atrial rate increases. This is designed to provide a more physiologic AVI at higher heart rates and to allow tracking of higher atrial rates (a shorter AVI decreases the TARP), thereby lessening the chance of a fixed-block upper rate response.
16. V = ventricular paced event.

17. VRP = ventricular refractory period. The timing cycle initiated by a ventricular sensed or paced event during which the ventricular sense amplifier is unresponsive to incoming signals. This is not the same as the ventricular blanking period (see information regarding this in Section **XVIII.B.7**).

CHAPTER 55

Christopher Ingelmo

Antitachycardia Devices

I. INTRODUCTION

A. The modern implantable cardioverter–defibrillator (ICD) is a multifunctional, multiprogrammable electronic device designed to abort life-threatening arrhythmias. It is programmed to automatically detect and manage episodes of ventricular tachycardia (VT), ventricular fibrillation (VF), or bradycardia. Current ICDs are able to deliver multitiered therapies, which may include a combination of antitachycardia pacing (ATP), cardioversion, and defibrillation. The devices also offer bradycardic support, which may include rate-responsive single- or dual-chamber pacing and automatic mode switch function. Modern ICDs are able to deliver resynchronization therapy, a significant advancement in the management of heart failure. The devices are also able to store electrograms (EGMs), which can be easily retrieved. This function can be of immense use for follow-up management of the patient and programming of the device.

Multiple clinical trials have demonstrated the efficacy of ICDs to accurately detect and manage sudden cardiac death (SCD). The ICDs are superior to conventional therapy, with medications in both primary and secondary prophylaxis of SCD. The majority of patients who have indications for an ICD implant are those with left ventricular (LV) dysfunction, both ischemic and nonischemic.

B. Mirowski first introduced the concept of an ICD in the 1960s, with the first human implant reported in 1980. The early ICD implantations required a thoracotomy approach for placement of an epicardial lead system. Subsequent advancements in device and lead technology over the last 30 years have significantly reduced the size of the pulse generator, yet improved the programmability and diagnostic data stored within the device. An improved understanding of VF, defibrillation, and cardiac pacing has resulted in the development of biphasic shock waveforms and transvenous pace/defibrillation lead systems that preclude the need for epicardial patches. As a result, modern ICDs are more compact devices, with expansive programming capability placed by a transvenous approach. The newest generation of devices has the added capability of trans-telephonic interrogation.

II. ICD COMPONENTS

A. The current-day ICD is a sophisticated and intelligent computer. It consists of a generator and leads. The ICD generator consists of a battery, capacitors, DC–DC converter using an oscillator rectifier mechanism, a microprocessor, and telemetry communication coils and their connections. The generator serves as an active electrode within the shocking configuration in most of the modern ICDs and is thus called the "hot can." The battery used in most of the ICDs is a lithium–silver vanadium oxide cell. This can generate approximately 3.2 V at full charge. Because most ICDs use two batteries connected in series, the full initial voltage is approximately 6.4 V. The generator has capacitors that can charge within 7 to 30 seconds to store up to 30 to 40 J of energy. This can be delivered to the heart within a 10- to 20-millisecond interval when therapy is required.

B. The three essential functions of the ICD—**tachycardia detection, tachycardia therapy, and bradycardia pacing**—are delivered through the active electrodes, which are the noninsulated segments of the leads. Most of the current-day leads have sensing and pacing electrodes at the tip and a distal (right ventricle) and proximal (superior vena cava) shocking coil. The function of ventricular sensing and pacing is achieved by a technology similar to that in pacemakers. This is done through two "dedicated bipolar" electrodes at the distal end of the right ventricular (RV) lead (tip/ring). Sometimes, it may be achieved by "integrated bipolar" electrodes, wherein the bipole is formed by the tip of the ventricular lead and the distal shocking coil (tip/coil). Ventricular pacing in biventricular ICDs is from the tip of the RV and LV leads, respectively, to either the ring (true bipolar) or the distal shocking coil (integrated bipolar). The sensing could be from both RV and LV leads but could give rise to false tachycardia detection due to the problem of "double counting." It is for this reason that the newer devices restrict the sensing function to the RV lead alone.

C. For the delivery of shock therapy, most systems now incorporate a combined RV coil, superior vena cava coil, and active pulse generator can or sometimes a single RV coil with a hot can active pulse generator. Modern technology makes it feasible to incorporate all these electrodes and coils in a single lead implantable in a manner similar to a pacemaker.

III. INDICATIONS AND CONTRAINDICATIONS

A. ACC/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities. These are the most current guidelines for the implantation of ICDs. The guidelines stratify the various indications as class I, class II (a and b), and class III on the basis of the data from clinical trials and opinion of a panel of experts.

B. Class I indications. These are clinical situations or conditions for which there is evidence and/or general agreement that ICDs are useful and effective.

(1) Survivors of SCD secondary to VF or hemodynamically unstable VT

(2) Syncope of unknown etiology with inducible VF or hemodynamically significant VT during electrophysiology study

(3) Structural heart disease and spontaneous hemodynamically unstable or stable VT

(4) Ischemic cardiomyopathy, New York Heart Association (NYHA) class I, and a left ventricular ejection fraction (LVEF) ≤ 30% who are at least 40 days post myocardial infarction (MI)

(5) Ischemic cardiomyopathy, NYHA class II or III with an LVEF ≤ 35% who are at least 40 days post-MI

(6) Ischemic cardiomyopathy, ejection fraction (EF) ≤ 40%, nonsustained ventricular tachycardia , and inducible VF or sustained VT at electrophysiology study

Nonischemic cardiomyopathy, NYHA class II or III, and LVEF ≤ 35%.

C. Class IIa indications. These are conditions for which there is conflicting evidence about the usefulness of ICD therapy, with the weight of evidence/opinion in favor of usefulness/efficacy.

1. Unexplained syncope with significant LV dysfunction and nonischemic cardiomyopathy

2. Normal or nearly normal LVEF with sustained VT

3. Patients with hypertrophic cardiomyopathy and at least one risk factor for SCD

4. Patients with arrhythmogenic RV dysplasia with at least one risk factor for SCD

5. Patients with long QT with syncope or VT while taking β-blockers

6. Patients waiting heart transplantation (nonhospitalized)

7. Patients with Brugada with a history of syncope or VT but no episodes of cardiac arrest

8. Patients with catecholaminergic polymorphic VT with syncope or sustained VT while taking β-blockers

9. Patients with cardiac sarcoid, giant cell myocarditis, or Chagas disease.

D. **Class IIb** (usefulness/efficacy is less well established by evidence/opinion)
   1. Nonischemic cardiomyopathy with an EF ≤ 35% and NYHA class I
   2. Long QT and risk factors for SCD
   3. LV noncompaction patients
   4. Patients with familial cardiomyopathy and a predisposition to SCD
   5. Patients with structural heart disease and syncope but with no identifiable etiology

E. **Class III indications/contraindications.** These are conditions for which there is a general agreement that ICDs are not useful and possibly harmful. These include patients with a structurally normal heart and syncope without any inducible ventricular arrhythmias. ICDs should also be avoided in patients with VT and a treatable/ablatable cause (Wolff-Parkinson-White syndrome, outflow tract VTs, fascicular VTs, etc.) or a reversible cause (acute MI, myocardial ischemia, electrolyte imbalance, drug toxicity, or trauma). It is also important to avoid using ICDs in patients with severe psychiatric illnesses or in patients with terminal illnesses, where the expected life span is less than 12 months. ICDs could do more harm than good in patients with incessant ventricular arrhythmias, where it is important to control the arrhythmia before ICD implantation to avoid recurrent painful shocks. ICDs are also contraindicated in patients with NYHA class IV heart failure that are drug refractory and are not candidates for heart transplantation or cardiac resynchronization therapy (CRT).

IV. IMPLANTATION

A. **Device implantation.** Currently, available devices are small enough to allow implantation in the left pectoral region. Animal studies have shown that the defibrillation efficacy of the hot-can ICDs is superior in the left pectoral or axillary regions followed by the right pectoral and then the abdominal sites. A right pectoral system may be necessary in patients who have vascular access problems on the left side or who have undergone pectoral surgery (e.g., mastectomy). For patients with high defibrillation thresholds (DFTs), additional lead placement, such as a subcutaneous array/coil, an azygous coil, a coronary sinus coil, or an epicardial patch, may be necessary. Epicardial patch placement is usually reserved for patients who have failed to meet implantation criteria with a transvenous lead system or if there has been previous bilateral pectoral or tricuspid valve replacement surgery.

   For pectoral implants, a single 2″ to 3″ incision is made transversely below the clavicle, about 1 cm below and parallel to the deltopectoral groove. Transvenous lead placement is achieved through a subclavian vein puncture or by cephalic vein cutdown. An "extrathoracic" subclavian vein puncture or cephalic vein cutdown for access minimizes the risk of pneumothorax and also the risk of lead failure due to subclavian crush injury.

B. **Lead placement.** The lead is advanced to the RV apex under fluoroscopic guidance, where the tip is secured via an active fixation screw or embedded in the trabeculae with passive fixation tines. It is important to assess the quality of signals at the time of implant, as it is the best guide to the adequacy of long-term sensing of the lead. The DFT is optimized with the lead placed at the RV apex; therefore, this position is often preferred even if there is compromise of the sensing thresholds. If there is already a pacemaker lead in the RV apex, then septal placement of the lead tip is chosen so that the lead tips are at maximal distance from each other to avoid device–device interactions. On occasion, placing an additional pacing-sensing lead in the right ventricle may be necessary when the defibrillation efficacy and pace-sense function of the leads are optimized at different locations.

C. **Threshold studies.** The lead is tested for pace-sense thresholds using an external high-voltage system analyzer or pacing system analyzer. In general, an acute pacing threshold of 2 V or less, R-wave amplitude of 5 mV or more, and lead impedance within the accepted range of the manufacturer (typically 300 to 1,200 Ω) are

necessary to meet the implant criteria. The lead is secured within the pocket with a suture sleeve tie-down. If the device uses an atrial and/or an LV lead, then these are implanted at this time. The leads are attached to the pulse generator and the system is placed in either a submuscular or a subcutaneous pocket. The pulse generator should be placed with excess lead coiled posteriorly to reduce the risk of damaging the leads at the time of generator change and to maximize the ability to communicate with an external programming wand. The device is then interrogated to assure appropriate communication. Pace-sense thresholds are again tested by telemetry to demonstrate consistency.

D. Defibrillation testing is best assessed by evaluating the DFT, which is defined as the lowest delivered shock strength required for successful defibrillation. A synchronized sinus test shock may be performed by delivery of a low-energy (<2 J) synchronized shock delivered on the QRS complex. This low-energy test allows the assessment of sensing as well as shock impedance (typically 35 to 90 Ω). For the purpose of defibrillation testing, VF is typically induced with a shock on T wave. Alternatively, or if shock on the T wave is unsuccessful, ultrafast burst pacing (30-millisecond intervals) or application of an alternating current may be used. Appropriate ICD detection and effective therapy are verified. In our lab, we typically start with a 10 to 15 J therapy, with subsequent therapies escalating in steps of 5 to 15 J. Usually a maximum of three device-based therapies are attempted before rescue with external defibrillation at maximum energy. Two successful therapies that are at least 10 J less than the maximal output of the device are generally required. In general, this approach identifies the level of energy required to achieve a 50% to 75% success rate of defibrillation. Defibrillation therapy is then programmed at a level at least 10 J over the DFT. Rarely, a patient may require the addition of a shocking coil in the superior vena cava, subcutaneous patch, or subcutaneous array to achieve an adequate safety margin.

E. Risks and complications. The risks involved with implantation are similar to those of pacemaker insertion. Operative risks include bleeding, pneumothorax, hemothorax, infection, myocardial damage, vascular/cardiac perforation, tamponade, thromboemboli, deep venous thrombosis, acceleration of arrhythmias, air embolism, and death. A rare but dangerous complication is the occurrence of electromechanical dissociation or refractory VF during DFT testing. Due to the nature of the procedure, a separate standby external pacemaker-defibrillator should be immediately available for rescue therapy should the implanted device fail to appropriately treat an arrhythmia. The overall mortality rate is much less than 1%. Late complications include chronic nerve damage, erosion, extrusion, fluid accumulation, infection, formation of hematomas/cysts, keloids, lead migration, lead dislodgment, and venous occlusion.

V. DEVICE REPLACEMENT

A. Battery status is determined by the measured voltage and this is retrieved with device interrogation. Generator replacement is generally recommended when the device reaches a battery voltage of around 2.6 V, termed elective replacement indicator. In such situations, the generator should be replaced within a few months. With continued depletion of the battery voltage, the generator reaches end of life, a situation that indicates a more urgent need for generator replacement as the battery voltage drops below 2.2 V. This may lead to longer charge times and incomplete or inappropriate function of the device.

B. Pulse generator replacement represents a vulnerable period for the ICD/lead system. A fourfold increased risk of infection has been reported with ICD pulse generator replacement. In the past, manufacturers have had multiple-lead models of variable pin lengths and diameters. Beginning in 1991, they adopted the 3.2-mm international pace-sense standard (IS-1) and the 3.2-mm defibrillation standard (DF-1). Prior to an attempted device replacement, assessment of the lead model should be done to verify that the appropriate replacement header or adapters are available at the time of surgery.

C. Leads may be inadvertently damaged during exploration of the pocket or during the exchange of pulse generators. Intraoperative assessment of lead function is imperative prior to introducing the replacement generator to the operative field. Replacement of a pace-sense or defibrillation lead may be necessary and requires the use of a different device header.

VI. TACHYCARDIA DETECTION AND THERAPY

A. EGM and tachycardia sensing. The ICD senses the intracardiac EGM signal via the implanted ventricular sensing electrodes. Recognition of a ventricular arrhythmia mainly depends on the analysis of the R-R intervals (heart rate is determined similarly). Accuracy of the EGMs depends on the health of the adjacent myocardium and appropriate contact. Accuracy also depends on far-field signals from the muscles, atrium, or other sources of electromagnetic interference. The sensed signals are passed through a band-pass filter that consists of high- and low-frequency cutoffs to represent true signal events. The accuracy of the signals in the newer devices has been further improved by analysis of the signal frequency, slew rate, amplitude, EGM width, autogain, and autothreshold. These variables are important in helping the device to differentiate VT and VF from other events like atrial fibrillation, sinus tachycardia, and other supraventricular tachycardias, thus reducing the incidence of spurious shocks.

Each EGM event and R-R interval is marked and detected, and there are various algorithms that attempt to identify the events as either normal or abnormal. The "abnormal" includes bradycardia that requires pacing, VT requiring ATP or low-energy synchronized shocks, or VF requiring defibrillation. Most of the algorithms depend on the ventricular rate criterion. Other variables, such as the suddenness of onset, variation in cycle length, and change in EGM morphology, help to increase the specificity for diagnosis but at some cost of reduced sensitivity. These should be adjusted and programmed based on the individual requirement and clinical scenario for every patient.

B. Event detection occurs if the device reaches a specified number of intervals programmed by the physician to detect VT or VF, at which point the ICD delivers the prescribed therapy. Most of the devices reconfirm the ongoing episode to avoid therapy for nonsustained events. After delivery of therapy, the device either confirms termination of the episode or meets criteria for redetection, and the next programmed therapy is delivered. The ICD automatically adjusts its sensitivity thresholds following sensed and paced events through an autogain mechanism. This allows the device to automatically adjust its sensitivity during a tachycardia episode in response to the changing amplitude of the ventricular signal.

C. Atrioventricular (AV) sequential devices incorporate programmable dual-chamber supraventricular criteria to exclude management of supraventricular tachyarrhythmias from inappropriate detection of VT or to identify concurrent VT and supraventricular tachycardia. Biventricular devices could pose problems of double counting and unnecessary therapies in patients with the older biventricular devices, where the sensed input is from both the RV and LV leads. The use of newer devices that have sensing inputs from only the RV leads should limit this problem. An additional feature of these devices is the capability to individually program the pacing output and timing of the RV and LV leads through separate ports.

D. Tachycardia therapy. Most devices allow for programming of several tachycardia zones. The VT zone is programmed with a lower detection cutoff that would include any clinical VT events. Ideally, the cutoff rate for the detection of tachycardia should be above the patient's maximal heart rate to avoid therapy for sinus tachycardia. ATP schemes include burst pacing and ramp pacing. Burst pacing sequences deliver a set of ventricular pulses at a fixed rate faster than that of the VT in an attempt to terminate the reentry VT by overdriving the circuit. Ramp pacing consists of a set of ventricular pulses in which each subsequent paced interval is incrementally shorter

than the preceding one. Although this is a more aggressive protocol, there is also a higher chance for the VT degenerating into VF with this therapy. Overall, some studies have shown about 90% success in termination of VT with ATP.

Following a failed ATP attempt, interburst decrement allows a more aggressive shortening of the intervals during either a burst or a ramp attempt. The first pulse of a burst or ramp sequence (S_1) is delivered at a calculated percentage of the tachycardia cycle length. The S_1 percentage cycle lengths, number of pulses, interburst decrement, and number of ATP attempts are all programmable features. In addition, cardioversion therapy (1 to 36 J) can be programmed in a VT zone. All VT zones have a programmable time limit on episode duration at which point the device defaults to the next zone. Also, if a tachycardia is accelerated to a faster arrhythmia, then the ICD will deliver the therapy appropriate for the rate of the accelerated tachycardia.

E. Defibrillation therapy. Successful ICD management of VF can only occur with defibrillation therapy. All devices are programmed with a VF zone due to the risk of acceleration with ATP or cardioversion. Because of the hemodynamic instability seen with fast VT or VF, most devices are typically programmed to manage any sustained episode with rates higher than 180 to 200 beats/min with defibrillation therapy. The device should be programmed with at least a 10-J safety margin over the DFT observed either at implant or during follow-up testing. Up to six additional shocks may be programmed, with maximal outputs programmed at the second or third shock and onward.

VII. BRADYCARDIA DETECTION AND THERAPY

A. All currently available ICDs provide basic VVI pacing with separate programmable post-shock lower rate limit and output. Some dual-chamber devices have been introduced with an atrial lead for diagnostic use only or for AV-synchronized pacing. These devices allow multiple programmable pacing modes, including single- and dual-chamber, fixed-rate, or rate-responsive pacing with automatic mode switch. These expanded pacing modes have obviated the need for a separate dual-chamber pacemaker. In addition, they may reduce the inappropriate shocks attributed to supraventricular tachycardia. Such devices may also have capabilities to detect and treat atrial arrhythmias in a manner similar to that for the ventricular arrhythmias. However, in patients without any pacing indications, it may actually be detrimental to pace the right ventricle, especially in patients with preexisting LV dysfunction. This has been well demonstrated in the Dual Chamber and VVI Implantable Defibrillator (DAVID) trial. Such patients should either be given a single-chamber ICD or, if there are indications for a dual-chamber ICD for tachycardia discrimination or atrial arrhythmias, be programmed for backup pacing in the VVI mode.

B. In AV-synchronized devices, the ICD can continue to sense tachyarrhythmias in both chambers regardless of the programmed bradycardic pacing mode. To maintain proper sensing, both atrial and ventricular sensing thresholds are adjusted with autogain. The ICD has multiple blanking periods to avoid post-pacing polarization, T-wave oversensing, and cross talk between chambers. To avoid undersensing of tachyarrhythmias, short cross-chamber blanking periods after paced events and no cross-chamber blanking after sensed events are necessary. The AV synchronous devices have programmable refractory periods available for bradycardia functions, but these refractory periods do not affect tachyarrhythmia detection.

VIII. MAGNET FUNCTION

A. Confusion abounds concerning the function of a magnet with ICDs. The pulse generator contains a reed switch that is closed when a magnet is placed over the device. Closure of the reed switch prevents delivery of tachyarrhythmia therapy. Unlike pacemakers, bradycardia pacing is not affected by the use of a magnet in ICDs. Normal device therapy resumes when the magnet is removed and the reed switch opens.

IX. DEVICE–DEVICE INTERACTION

A. Device–device interaction remains a significant issue when multiple-lead systems or devices are used. When a new lead is placed, the lead should be positioned as far from the other leads as possible (at least 2 cm). A dedicated bipolar sensing lead is preferred to minimize the potential of far-field oversensing of the alternate pacing lead.

B. During the implantation procedure, the devices should be tested for device–device interaction. To simulate a worst-case scenario, the pacemaker is programmed in a unipolar configuration at high output. The real-time ICD EGM and marker channels are observed for oversensing of the pacemaker output, resulting in double counting of the paced QRS complex. This may lead to an inappropriate ICD discharge. Defibrillation testing is performed with the pacemaker programmed to DOO/VOO at high output to verify appropriate VF detection and therapy. Pacing stimuli may lead to ICD undersensing of VT/VF, with interpretation of the pacing artifact as "sinus rhythm" and failure to recognize the underlying arrhythmia. In addition, the ICD may affect the pacemaker by resetting the pacemaker pulse generator with a high-voltage shock. The pacemaker is programmed with the sensor "on" during an ICD high-output defibrillation test. The pacemaker is subsequently interrogated to verify appropriate communication and programmed mode. Whenever multiple devices are present and inappropriate ICD discharges are suspected, electrophysiology lab testing for device–device interaction is warranted. Device–device interaction should also be considered when a patient presents with resetting of the programmed mode, output configuration, or failure of communication with the device.

X. MANAGING AND FOLLOWING PATIENTS

A. In the United States, the government mandates patient registration and tracking. Once registered, a patient receives a permanent identification card to carry at all times. A MedicAlert is strongly encouraged. Manufacturer guidelines suggest that patients should follow up every 1 to 4 months depending on clinical status. Even if trans-telephonic follow-up is available, it should be supplemented by clinic visits. Patients should be informed that they are likely to receive therapies. At the follow-up visit, a history of symptoms that might suggest tachyarrhythmias should be obtained. The diagnostic and episode data should be reviewed. Current devices also include stored-episode EGMs to allow review of aborted shocks as well as delivered therapies. Device pacing and sensing thresholds should be obtained. There are no specific guidelines for follow-up testing of ICD defibrillation function. In general, patients experiencing device activation should be evaluated shortly after the event to assess for safe and appropriate device function. When device function or concomitant antiarrhythmic therapy is modified, an evaluation of the sensing, pacing, and defibrillation thresholds is often necessary. Practice patterns vary widely regarding empirical device programming and electrophysiologic testing of modified ICD programming. Some sources recommend that operating a motor vehicle should be avoided for 6 months following a symptomatic arrhythmic event.

B. In general, ICD pulse generators have a 4 to 6 year longevity depending on usage. The programmer allows evaluation of battery status. As the device approaches the elective replacement interval, follow-up visits should be intensified. In general, once the device reaches the elective replacement interval, it operates normally for at least 3 months depending on the frequency of therapy. Capacitor deformation occurs during periods when no shocks are delivered and results in longer charge times as well as decreased battery longevity. Current ICDs perform an automatic capacitor reformation that charges the capacitors and delivers the energy to an internal test load. This function improves subsequent charge times and battery longevity. Capacitor reformations should be conducted manually every 3 to 6 months if not conducted automatically.

C. Typically, 40% of patients receive a therapy within the first year after implantation and 10% per year thereafter. If multiple ICD discharges are experienced, medical attention should be sought emergently. **Failure to discriminate between ventricular and supraventricular rhythms is the most common reason for inappropriate shocks**. It is important to evaluate the patients for appropriateness of therapy. The most common cause of inappropriate shocks is atrial fibrillation with a fast ventricular rate. Shocks delivered during physical exertion noted to have gradually increasing heart rates and gradually decreasing V-V intervals suggest sinus tachycardia. Therapy is likely to be inappropriate in this setting also. Ideally, the cutoff rate for the detection of tachyarrhythmias should be greater than the patient's maximal heart rate. In many cases, the VT rate falls within the patient's achievable sinus rate. Programmable enhancements, such as sudden onset and sustained high rate, can allow sinus tachycardia overlap into the VT zone without delivery of an inappropriate shock. Additional enhancements such as morphology discrimination of the ventricular EGM as well as the introduction of dual-chamber devices with timing intervals, marker channels, and mode-switching capabilities are likely to improve the specificity of device therapy.

D. In the event of multiple ICD discharges, a magnet can be used to inhibit ICD therapy so that the underlying rhythm can be appropriately assessed and managed. The device should be interrogated as soon as possible to assess ICD function and facilitate diagnosis. If a supraventricular tachycardia is present, then it should be managed as medically appropriate. For patient comfort, the magnet should be left in place to inhibit ICD therapy until the device can be reprogrammed or the supraventricular tachycardia is terminated. If VF is present, the device is assumed inoperable and cardiopulmonary resuscitation with external defibrillation should be applied.

E. Patients receiving ICDs may suffer from significant psychological and emotional disturbances. Education and psychological support are beneficial in improving these patients' quality of life.

XI. ELECTROMAGNETIC INTERFERENCE. Patients should be counseled to avoid sources of electromagnetic interference because such interference may cause the pulse generator to become inhibited and either fail to deliver appropriate therapy or deliver inappropriate therapy. Potential sources of electromagnetic interference include industrial transformers, radiofrequency transmitters such as radar, therapeutic diathermy equipment, arc welding equipment, toy radio transmitters, antitheft devices, and magnetic security wands. The safe use of medical technologies such as electrosurgery, lithotripsy, external defibrillation, and ionizing irradiation can be accomplished by deactivating the device before the event. Shielding of the device is also appropriate when possible. The device should be evaluated for appropriate operation following exposure. Magnetic resonance imaging is contraindicated. Reports of interference created by cellular phones may be related to either a magnetic field from within the phone or the radiofrequency signal generated by the phone. It is suggested that if a patient with ICD wishes to use a cellular phone, it should be held to the ear opposite the device and carried at least 6″ to 12″ from the pulse generator; in addition, the phone should not be carried in a pocket close to the device.

XII. FUTURE. ICD implantation rates have risen tremendously over the last two decades and are expected to rise further with evolving therapies and indications. Multiple clinical studies have demonstrated the role of ICDs in the primary and secondary prevention of SCD. Multiple trials have also demonstrated the role of an ICD in combination with CRT in reducing mortality and hospital admissions in patients with heart failure. Improvements in electronic technology will continue to expand programming capabilities of these devices while reducing their size. ICD lead technology is also expected to improve, thereby decreasing the number of lead-related complications. Leadless systems are in clinical trials and may be an option for select patients in the future.

CHAPTER 56

John Rickard

Cardiac Resynchronization Therapy

I. INTRODUCTION. The prevalence of heart failure (HF) in the United States has increased considerably in the past two decades as a result of the aging population and better medical management of left ventricular dysfunction (LVD). Unfortunately, medical therapy is not completely effective in preventing or reversing the progression of HF, and as a result, patients with advanced HF have limited options. A subset of patients with systolic LVD who have associated ventricular conduction delay are at highest risk for HF progression and a poor overall outcome. Since the late 1970s, various investigators have shown that left bundle branch block (LBBB), right ventricular (RV) pacing, or intraventricular conduction delay (IVCD) is associated with a less favorable hemodynamic profile in those with LVD and even in normal subjects. **The mechanism for this phenomenon is thought to be due to asynchronous and inefficient contraction of opposing areas of the ventricular myocardium. More importantly, restoring synchronization, either via simultaneous pacing of the RV apex and the left ventricular (LV) free wall or with timed LV free wall activation, can lead to a significant hemodynamic improvement.** In 1994, two investigators in Europe applied cardiac resynchronization therapy (CRT) in the clinical setting for the first time. Subsequent small observational studies suggested benefit from synchronous pacing. Larger randomized clinical trials confirmed these findings. CRT was first approved for maximally medically managed patients with persistent New York Heart Association (NYHA) class III or IV HF symptoms due to severe LVD associated with prolonged QRS duration. Further randomized studies, powered for mortality, showed a significant survival benefit with CRT or the combination of CRT with a defibrillator (CRT-D). More recently, CRT has been shown to be beneficial in less symptomatic patients. Unfortunately, not all patients who are selected for CRT based on current guidelines respond. Furthermore, some patients who would not be selected for CRT based on the current guidelines may actually benefit from this therapy. One of the major current challenges in this field is the optimal definition of the appropriate and cost-effective use of this expensive technology.

II. MECHANISM OF LV DYSSYNCHRONY. The normal pattern of electrical activation of the ventricular myocardium, once the impulse passes through the atrioventricular (AV) node, starts in the His bundle, followed by simultaneous activation of the right and left bundles of the Purkinje system and then by myocardial depolarization. The Purkinje system is electrically isolated from the rest of the myocardium until it reaches its exit points at the Purkinje–myocardial junctions. As a result, typical LV myocardial activation occurs from the apex to base, simultaneously in the septum and in the LV free wall, and is described as synchronous. Due to tight electromechanical coupling of the myocardium, synchronous ventricular activation is followed by synchronous ventricular contraction.

In the setting of conduction delay, the electromechanical coupling of the heart is disrupted, leading to dyssynchrony. Over time, electromechanical uncoupling leads to impaired stroke volume, worsened mitral insufficiency, prolonged LV isovolumetric

events, and impaired diastolic filling. These effects contribute to adverse remodeling in the already impaired heart, creating a vicious cycle that perpetuates this process into more advanced HF. As a result, when comparing patients with similar degrees of LVD, **those with conduction delay have a worse overall prognosis**. CRT has been shown to reverse this deleterious process. Synchronized pacing has been shown to improve LV function without increasing oxygen demand, suggesting that the improvement is related to better efficiency of the LV chamber.

Interestingly, dyssynchronous activation and contraction have an undesirable effect in patients ***without*** LV systolic dysfunction also. When compared with normal controls, patients with LBBB have a lower ejection fraction (EF), are more likely to develop HF, and have a tenfold greater cardiovascular morbidity and mortality risk. In some patients (patients with chronic LBBB, frequent premature ventricular contractions, or chronic RV pacing), the conduction delay in and of itself may cause deterioration in the EF. In this population, treatment with CRT can have profound effects potentially normalizing the LV function.

III. TYPES OF DYSSYNCHRONY

A. AV dyssynchrony. In the setting of PR or QRS prolongation, the atrial contribution to LV filling is abnormal. Atrial systole occurs too early with respect to ventricular diastole, leading to early truncation of passive LV filling. Early atrial systole also causes an early rise in diastolic ventricular pressure, leading to diastolic mitral regurgitation (MR). Compromised LV filling and MR cause lower cardiac output. AV synchronization can improve cardiac output in HF by as much as 20%.

B. Interventricular dyssynchrony. Early RV activation present during LBBB, IVCD, or RV pacing leads to early RV contraction, creating a pressure gradient between the RV and LV that negatively affects LV filling, which translates to a decrease in LV preload and a subsequent decrease in cardiac output. In the early development of CRT, interventricular dyssynchrony was thought to be a major contributor to adverse events in patients with HF and conduction disease. More recently, however, interventricular resynchronization has not been shown to be of significant benefit, clinically calling the role of interventricular dyssynchrony in the failing heart into question.

C. Intraventricular dyssynchrony. In the presence of conduction delay, there is a substantial delay in the activation of certain LV segments compared with others, leading to an inefficient back-and-forth mechanical interaction that results in inefficient myocardial contraction. In the case of a native LBBB for example, there is a significant delay in activation between the early activated septum and the late activated posterolateral wall, often resulting in profound delays between segments. **Mitigation of intraventricular dyssynchrony** is currently thought to be the primary mechanism of improved myocardial performance with CRT.

IV. ASSESSMENT OF DYSSYNCHRONY (see Table 56.1).

While CRT has been established as an effective therapy for patients with conduction delay and LVD, approximately 30% of patients meeting current implantation criteria fail to respond (depending on one's definition of response). This has spawned a major research effort to identify dyssynchronous contraction preimplantation to refine appropriate patient selection for this procedure. In addition to the three varieties of dyssynchrony already discussed, dyssynchrony can also be broken into "mechanical" and "electrical." Electrical dyssynchrony refers to delays in depolarization from one segment to another, whereas mechanical dyssynchrony refers to contraction delays from one segment to another. While the two are presumed to be closely linked, **current measures of electrical and mechanical dyssynchrony have often shown poor agreement**. For example, almost all clinical trials have used prolonged QRS duration, a crude marker of electrical dyssynchrony, as a requisite for inclusion. The relationship, however, between QRS duration and various

TABLE 56.1 Commonly Used Echocardiographic Measurements of Dyssynchrony

Method	Measurement	Value (milliseconds)
M-mode	Septal to posterior wall delay	> 130
Pulsed tissue Doppler	Opposing wall delay onset velocity	> 60
Color tissue Doppler	Opposing wall delay peak velocity	> 65
Color tissue Doppler	12-Segment standard deviation	> 34
Tissue Doppler radial strain	Septal to posterior wall delay	> 130
Tissue speckle tracking radial strain	Septal to posterior wall delay	> 130
Three-dimensional echocardiography	12-Segment standard deviation	> 36

measures of mechanical dyssynchrony has been poor. Studies have revealed that up to 30% of patients with a prolonged QRS duration do not have mechanical dyssynchrony as assessed by magnetic resonance imaging (MRI) or echocardiography, whereas up to 30% of patients with a normal QRS duration and symptomatic HF have evidence of mechanical dyssynchrony on echo or MRI and could potentially benefit from resynchronization therapy. Currently, the development of new measures of both electrical and mechanical dyssynchrony is an area of intense research. While newer, noninvasive measures of electrical dyssynchrony other than the QRS duration are on the horizon, currently, the bulk of research on dyssynchrony has been dominated by the various metrics of mechanical dyssynchrony, mostly using various echocardiographic techniques.

A. Echocardiographic assessment of dyssynchrony. The assessment of cardiac mechanical dyssynchrony was initially made with M-mode and pulsed-wave Doppler. Subsequently, tissue Doppler imaging (TDI) and tissue synchronization imaging have been used. More recently, three-dimensional echocardiography and speckle tracking technology have shown considerable promise. The main difficulty with all measures of mechanical dyssynchrony has been reproducibility across centers. In the large, multicenter PROSPECT trial, multiple echocardiographic measures of mechanical dyssynchrony were tested. **None, however, were found to be both a sensitive and a specific predictor of subsequent response to CRT**. Technical and interpretative variability across centers was thought to be a major reason behind the only modest predictive ability.

1. **Pulsed-wave Doppler** has been used to assess interventricular dyssynchrony by measuring the time delay between initiation of RV and LV ejection, known as the presystolic ejection period. One advantage of this technique is good feasibility and reproducibility. While values > 40 milliseconds are considered to be abnormal, the clinical utility of this measure remains to be proven.
2. **Septal to posterior wall motion delay** as assessed by **M-mode** in the parasternal long or short axis view has been used to detect intraventricular dyssynchrony. A value > 130 milliseconds has been associated with a greater response to CRT in terms of symptomatic improvement, LV remodeling, and EF increase. Advantages include the ability to perform this measure on all echocardiographic systems without the requirement of specialized software. Unfortunately, this parameter has significant limitations. It evaluates dyssynchrony in only two segments of the myocardium: the septum and the posterior wall. Additionally, it may be difficult to obtain in up to 40% of patients due to poor acoustic windows

as one must be perpendicular to the myocardial walls, which is often difficult in patients with low parasternal windows.

3. **Tissue Doppler imaging.** This technique uses pulsed-wave Doppler to record myocardial velocities at the basal septum and the basal lateral wall as close as possible to the mitral valve annulus in the four-chamber view. Time from the onset of the QRS to the onset of systolic velocity or to the peak of systolic velocity is measured. So too is the difference in these measurements between the septum and the lateral wall. Values > 62 milliseconds for time to systolic velocity initiation and 65 milliseconds for time to peak systolic velocity are abnormal and have predicted a favorable clinical and echocardiographic response to CRT. TDI has excellent temporal resolution and does not require endocardial border identification for determining the degree of delay. The limitations of TDI are as follows: (1) occasional difficulty in identifying the true peak of systolic velocity and (2) because segments are not assessed simultaneously, heart rate variability and respiration can lead to false comparisons. To better deal with these limitations, computer software has been developed that allows postprocessing of Doppler data so that all of these measurements are determined from one image. Additional views (apical three-chamber and apical two-chamber) may be used to increase the number of myocardial segments assessed. This technique improves both specificity and sensitivity in the identification of mechanical dyssynchrony, as compared with older, less sophisticated methods.

   Another major problem with current methods of TDI is that they assess systolic motion only in the longitudinal plane of the heart and, therefore, may be prone to artifact from tethering and pulling. The heart contracts in three different planes: longitudinal, radial, and rotational. The latter two are not assessed by conventional TDI but have a greater contribution to ventricular contraction than the longitudinal plane.

4. **Three-dimensional imaging.** The development of three-dimensional echocardiographic technology now allows the measurement of endocardial wall motion in reference to a center point. Using computer assistance, the endocardial border is tracked. Only the end-systolic and end-diastolic positions of the ventricular apex and mitral annulus must be determined by the operator. This technique permits the calculation of the three-dimensional dyssynchrony index, which quantifies mechanical dyssynchrony as the standard deviation of the time to minimum systolic volume as a percentage of the cardiac cycle length. While three-dimensional motion delay imaging has shown promise as predictive of subsequent reverse remodeling following CRT, it remains limited by the need for good image quality and a stable heart rhythm.

B. New echocardiographic indices of mechanical dyssynchrony. Newer echocardiographic techniques focus on eliminating the shortcomings of longitudinal TDI, namely, the tethering and pulling artifact, and lack of radial and rotational strain assessment.

1. **Strain imaging** performed in the four-chamber and parasternal short axis views incorporates velocity sampling in two nearby points. The sampled velocity difference divided by the separation distance is proportional to strain rate, which when integrated over time can provide the strain value. Strain, unlike velocity, does not depend on tethering or pulling of the myocardium. The major limitation of this technique is that it is time consuming and requires extensive off-line postprocessing.
2. **Speckle tracking.** Speckle tracking relies on the automated tracking of unique acoustic backscatter during standard grayscale imaging. Both strain and its planar dimensions may be assessed using semiautomated off-line analysis, which improves reproducibility and feasibility. This technique is promising and is currently being used as a measure of mechanical dyssynchrony in ongoing clinical trials.

C. Alternative modalities for dyssynchrony assessment. Tagged MRI is ideal for measuring strain; however, due to its high cost, high level of complexity, and contraindications in patients with pacemakers or implantable cardioverter–defibrillators (ICDs), it is of limited use with respect to dyssynchrony assessment.

V. ROLE OF CRT. The primary role of CRT is **to improve systolic and diastolic LV performance via an improvement in chamber efficiency**, thereby leading to symptomatic improvements in patients with medication refractory HF. The **systolic improvement** is usually noticed **within a week** of device implantation. In clinical trials, the **EF improved by an average of about 5%** with a significant improvement in MR and was accompanied by symptomatic improvement, as evidenced by increased 6-minute walk time and quality of life index score (QOLS). **The remodeling of the LV takes at least 3 or more months**. On average, the LV systolic and diastolic dimensions decrease significantly following prolonged CRT. In studies in which biventricular (Bi-V) pacing was switched off after prolonged synchronized pacing, the systolic benefits disappeared rapidly; however, the LV dimensions were maintained for a longer period of time, suggesting that actual LV remodeling took place during CRT. There is also evidence that CRT may lead to electrical remodeling of the heart. In patients with LBBB or IVCD, CRT led to shortening of the duration of the native QRS complex. More recently, evidence from randomized clinical trials powered for mortality, in addition to symptomatic improvement, supports the use of CRT alone or in combination with an ICD in patients with ischemic and nonischemic etiologies of severe LVD.

VI. SUMMARY OF MAJOR CLINICAL TRIALS OF CRT. Most clinical trials evaluating CRT have addressed its role in patients in normal sinus rhythm (NSR) with severe LVD, class III to IV HF symptoms refractory to medical therapy, and indirect evidence of mechanical dyssynchrony represented by prolonged QRS duration (on average, > 120 milliseconds). More recently, large trials have focused on the benefits of CRT in patients with less symptomatic HF (NYHA classes I and II).

A. PATH-CHF. A longitudinal crossover study of 41 patients evaluating CRT (Bi-V or LV pacing) versus no therapy. Primary end points of peak Vo_2, 6-minute walk, NYHA class, and QOLS significantly improved during CRT.

B. MUSTIC. A small prospective randomized trial powered for symptomatic improvement as measured by hospitalization, 6-minute walk, and QOLS in patients in NSR or with atrial fibrillation at the time of enrollment. The trial showed significant improvements with CRT, and the benefit was similar in NSR and atrial fibrillation.

C. MIRACLE. The MIRACLE trial, completed in late 2000, randomized 453 patients with advanced HF and a QRS duration ≥ 130 milliseconds to CRT versus conventional therapy for HF. The trial revealed significant improvements in peak Vo_2 consumption, 6-minute hall walk, QOLSs, EF, NYHA class, and treadmill exercise times with CRT compared with controls. This trial led to the approval of CRT devices by the Food and Drug Administration.

D. MIRACLE-ICD. Very similar to MIRACLE, the MIRACLE-ICD trial was a moderate-sized prospective randomized trial evaluating the safety and efficacy of combining CRT with ICD therapy for a composite end point of mortality, hospitalization, and symptomatic improvement. At 6 months follow-up, the CRT-ICD arm had a significant improvement in the composite end point. Combining CRT with ICD was deemed safe.

E. CARE-HF. The CARE-HF was a large, open-label randomized controlled trial powered to assess mortality benefit with best medical therapy plus CRT versus medical therapy alone in patients with ischemic and nonischemic etiology of LVD. In addition to the conventional dyssynchrony criteria of QRS duration > 150 milliseconds, the trial was the first to implement echocardiographic markers of mechanical dyssynchrony in those patients with QRS duration between 120 and 150 milliseconds. At 3 years of

follow-up, the primary end point of all-cause mortality and hospitalization was significantly different in favor of the CRT group. Furthermore, the secondary end point of all-cause mortality reached statistical significance after 3 years of follow-up, and the survival curves continued to separate. The number needed to treat with CRT to save one life was estimated at nine patients.

F. COMPANION. A large, open-label randomized (1:2:2) prospective trial powered for mortality and hospitalization benefit in patients with ischemic and nonischemic etiologies of LVD comparing medical therapy versus CRT versus CRT-D. In addition to conventional QRS criteria for CRT, patients also had to have had one episode of hospitalization for HF in the year prior to randomization. The primary end point of all-cause mortality and hospitalization was significantly different in the device groups as compared with the medically treated group. The secondary end point of all-cause mortality was significantly different in the CRT-D group as compared with the medical controls. The CRT group showed a strong trend toward mortality benefit that did not reach statistical significance. The trial was not powered to compare mortality benefits between the two device groups. In the CRT-D group, the mortality benefit was noticed shortly after the beginning of the trial, as compared with 6 to 12 months after study initiation in CARE-HF. The early mortality benefit in this trial was thought to be ICD related. The later benefits were attributed to both ICD and CRT therapies. The results of this trial led to approval of combined CRT-D therapy in the above population of patients.

VII. MAJOR TRIALS OF CRT IN MINIMALLY SYMPTOMATIC HF

A. REVERSE. The REVERSE study, published in 2008, was a large randomized, double-blind trial designed to assess whether CRT in addition to medical therapy could delay progressive myocardial remodeling and/or prevent HF progression. The study enrolled 610 patients with a 2:1 enrollment design such that 419 patients received a CRT-D device and 191 patients received an ICD alone. Inclusion criteria for the study were NYHA class I or II symptoms, a left ventricular ejection fraction (LVEF) ≤ 40%, a left ventricular end-diastolic dimension ≥ 55 mm, NSR, and a QRS duration ≥ 120 milliseconds. The primary end point of REVERSE was a novel clinical composite end point developed by Packer and colleagues, which rates patients as "improved," "unchanged," or "worsened" based on the combination of mortality status, hospitalizations due to HF, withdrawal of consent, and worsening NYHA class. The American arm of the study concluded at 12 months, with the European arm proceeding to 24 months. While there was no difference in the primary end point at 12 months, patients in the CRT arm derived significantly greater reductions in the left-ventricular end-systolic volume index and the left-ventricular end-diastolic volume index, respectively, and improvement in LVEF compared with those without CRT. During the 12-month follow-up period, there was no difference in mortality between the two groups; however, CRT significantly lowered HF hospitalizations. In the European arm of the trial in which follow-up was continued for an additional year, the benefit of CRT in inducing reductions in LV volumes and improvement in LVEF persisted at 24 months.

B. MADIT-CRT. MADIT-CRT, published in 2009, sought to determine the impact of CRT on HF hospitalizations and all-cause mortality in patients with NYHA class I or II HF symptoms. This multicenter, unblinded study randomized 1,820 patients in North America and Europe with an LVEF ≤ 30%, NYHA class I or II symptoms (patients with nonischemic cardiomyopathy and NYHA class I symptoms were excluded), NSR, and a QRS duration ≥ 130 milliseconds to a CRT-D device or an ICD alone. The primary end point for the study was death from any cause or a nonfatal HF event. At a mean follow-up of 2.4 years, patients in the CRT arm had a significantly lower incidence of the primary end point compared with the ICD alone arm. Similar to what was shown in REVERSE, patients in the CRT arm of

MADIT-CRT realized significantly greater improvements in myocardial structure and function compared with those without CRT.

C. RAFT. The RAFT trial which began enrollment in 2003 was a large, double-blinded, randomized controlled trial of 1,798 patients with NYHA class II or III symptoms, an LVEF ≤ 30%, and a QRS duration ≥ 120 milliseconds (or a paced QRS > 200 milliseconds), which compared therapy with CRT-D versus that with an ICD alone. Originally, the trial sought to determine whether CRT in addition to an ICD would improve survival in patients with class II and III symptoms. After publication of the CARE-HF trial and subsequent guideline changes, however, the protocol was altered in early 2006 to include only patients with NYHA class II symptoms. Of 894 patients receiving a CRT-D device in the RAFT trial, 79.2% had NYHA class II symptoms. For inclusion, patients had to either be in NSR or have rate-controlled permanent atrial fibrillation or flutter. The primary end point of all-cause death or HF hospitalization occurred in 33.2% of the CRT-D group and in 40.3% of the ICD only group over a follow-up of 40 ± 20 months. In looking at only patients with NYHA class II symptoms, patients in the CRT arm had reductions in the primary end point as well as in both cardiovascular and all-cause mortality and hospitalizations due to HF.

VIII. NONRESPONDERS.

Up to **30% of patients who receive CRT based on current QRS criteria fail to benefit from the therapy depending on one's definition of response**. Their symptoms do not improve or worsen, and there is no echocardiographic evidence of reverse ventricular remodeling. A clear etiology of the lack of improvement from CRT in those patients has not yet been elucidated. One of the possibilities is that QRS duration alone is not a good indicator of mechanical dyssynchrony, and some patients, despite prolonged QRS duration, do not have mechanical dyssynchrony and worsen when Bi-V pacing is commenced. In subjects with normal baseline LV contraction, Bi-V or LV free wall pacing has an inferior hemodynamic profile when compared with native conduction. Therefore, it becomes important that CRT be only offered to those that truly have asynchronous contraction.

Another potential explanation for the lack of CRT benefit in certain patients is the presence of myocardial scar in the LV free wall territory. Areas of fibrous myocardium are electrically and mechanically nonviable; therefore, pacing at those sites may be of little value.

Lead position may play an important role in nonresponse. Typically, in nonischemic dilated cardiomyopathy with LBBB, the posterobasal segment has the most delayed activation and contraction. This is not always the case in patients with ischemic etiology of LVD, where occasionally the inferior wall becomes activated the latest. It is conceivable that, due to limitations in the myocardial venous system, inadvertent placement of the LV lead in an area that is not significantly delayed may lead to adverse hemodynamic effects. Trials are underway using echocardiographic techniques to determine the latest activated segment with implanters targeting placement of the LV lead in or near this segment.

IX. CURRENT GUIDELINES AND RECOMMENDATIONS.

Based on the inclusion criteria from the available large randomized trials at that time (see Table 56.2), the AHA/ACC 2008 Guideline Update for the Diagnosis and Management of Chronic Heart Failure in the Adult gives CRT a class I indication (level of evidence A) in patients with ischemic or nonischemic etiology of depressed LV function, EF ≤ 35%, severe HF symptoms, and NYHA class III or IV, on optimal medical therapy, in sinus rhythm with wide QRS complex ≥120 milliseconds, and with LV end-diastolic diameter ≥ 55 to 60 mm. The Task Force for Cardiac Pacing and Cardiac Resynchronization Therapy of the European Society of Cardiology, in collaboration with the European Heart Rhythm Association, provides the following recommendations for CRT.

TABLE 56.2 Current Recommendations for the Use of Cardiac Resynchronization Therapy in Patients with Heart Failure

Recommendation	Class	Level of evidence
Symptomatic HF (NYHA class III or ambulatory class IV) despite optimal medical therapy, with an LVEF ≤ 35%, normal sinus rhythm, and a wide QRS complex (≥ 120 milliseconds), should be treated with CRT/D	I	B
Symptomatic HF (NYHA class III or ambulatory class IV) despite optimal medical therapy, with an LVEF ≤ 35%, and a frequent dependence on ventricular pacing should be treated with CRT/D	IIa	C
Symptomatic HF (NYHA classes III or ambulatory class IV) despite optimal medical therapy, with an LVEF ≤ 35% and atrial fibrillation, should be treated with CRT/D	IIa	B
Symptomatic HF (NYHA class I or II) despite optimal medical therapy, with an LVEF ≤ 35%, who are undergoing implantation of a permanent pacemaker or ICD with anticipated ventricular pacing should be treated with CRT	IIb	C
Asymptomatic patients with reduced EF in the absence of other indications for pacing should not be treated with CRT/D	III	B
CRT is not indicated in patients whose functional status and life expectancy are limited by predominantly noncardiac conditions	III	C

CRT, cardiac resynchronization therapy; CRT/D, CRT with a defibrillator; EF, ejection fraction; HF, heart failure; ICD, implantable cardioverter–defibrillator; LVEF, left ventricular ejection fraction; NYHA, New York Heart Association.

Adapted from the ACC/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm.

A. The use of CRT or CRT-D is recommended in patients with HF who remain symptomatic in NYHA classes III–IV despite optimal medical therapy and with an LVEF ≤ 35%, LV dilation with LV end-diastolic diameter > 55 mm, NSR, and wide QRS complex (≥120 milliseconds) (class I, level of evidence A for CRT; class I, level of evidence B for CRT-D).

B. The use of CRT is also recommended in patients with HF with NYHA classes III–IV despite optimal medical therapy and with an LVEF ≤ 35%, LV dilation, and a concomitant indication for permanent pacing (first implant or upgrade of conventional pacemaker) (class IIa, level of evidence C).

C. The use of CRT is also recommended in patients with HF who remain symptomatic in classes III–IV despite optimal medical therapy and with an LVEF ≤ 35%, LV dilation, permanent atrial fibrillation, and indication for AV junction ablation (class IIa, level of evidence C).

D. The use of CRT is also recommended in patients with HF who remain symptomatic in classes III–IV despite optimal medical therapy and with an LVEF ≤ 35%, QRS ≥ 130 milliseconds, permanent atrial fibrillation, and indication for AV junction ablation (class IIa, level of evidence C).

X. IMPLANTATION PROCEDURE. Unlike conventional transvenous pacemaker or ICD implantation that requires lead placement in the right atrium and/or the right ventricle only, Bi-V pacing requires LV lead implantation. Initially, this was achieved via a

thoracotomy; however, currently up to 98% of Bi-V devices are placed via a transvenous approach. Although now used infrequently, some patients are still referred for a thoracotomy after a failed transvenous approach. Because most patients who qualify for CRT are also candidates for an ICD, current CRT devices have a combined pacemaker/ICD capability. The hybridization of CRT and ICD therapy increases the complexity of programming, follow-up, and troubleshooting of such devices.

The procedure is performed in an electrophysiology laboratory under sterile conditions. All patients receive preprocedural antibiotics at least 30 minutes before the procedure. A subcutaneous pocket is first prepared, making sure that appropriate hemostasis is achieved. Bi-V device implantation, due to the increased risk imposed by possible coronary sinus (CS) perforation, requires complete reversal of anticoagulation. Typically, a cephalic or axillary vein approach to venous access is used. The right atrial and RV leads are implanted in a fashion similar to a pacemaker or ICD implantation. The LV lead is placed through the CS into a CS branch on the lateral free wall of the left ventricle. Performing an occlusive CS venogram may help identify the appropriate vein. Various sheaths, catheters, and guidewires are available to cannulate the CS and advance the pacing lead into the appropriate vein. While the optimal site for LV lead placement is controversial, many experts agree that anterior and apical positions are suboptimal. Once the lead is advanced, its location should be confirmed by fluoroscopy, typically in the left anterior oblique (LAO) view. The goal is to document base to mid-posterolateral LV lead placement and maximal LV–RV lead separation in the LAO view. A steep angulation in the LAO view tends to be most accurate. It has been shown that LV–RV interlead distance on the **lateral chest radiograph** is predictive of CRT response. Pacing thresholds are acceptable if < 3 V at 0.5 milliseconds. Diaphragmatic capture is excluded by high-voltage pacing. If high pacing threshold or diaphragm capture occurs, the lead should be repositioned. CS trauma is frequent during lead placement, and it may range from dissection to frank perforation. Because the pressure in the venous system is low, serious sequelae are unusual and cardiac tamponade rarely results. After adequate LV lead placement and confirmed appropriate LV lead function, care must be taken during guidewire, CS platform, and stylet removal, so as not to disrupt lead position. Lead dislodgement occurs in as many as 5% to 10% of implantations. The time frame for the majority of dislodgements is the first 24 to 48 hours postimplantation, when patients resume activity. For that same reason, patients are encouraged to ambulate while still in-house to prevent any out-of-hospital dislodgement, which may have more serious consequences.

XI. PROGRAMMING AND FOLLOW-UP. Currently, multiple configurations for Bi-V pacing exist. The available pacing configurations vary by device manufacturer. Changing configurations for pacing can be very useful in cases of poor thresholds or diaphragmatic stimulation.

Ventricular pacing must be **continuous** during CRT in order to obtain maximal benefit. Typically, DDD mode with a short AV delay (80 to 110 milliseconds) to prevent native conduction is employed. If atrial pacing is undesirable due to increased incidence of atrial fibrillation or altered left-sided AV timing, VDD mode may be used. Ventricular pacing is usually simultaneous or with a slight V-V delay. Given the two ventricular inputs (right ventricle and left ventricle), one could foresee that ventricular timing cycles could be quite complex during Bi-V pacing. Therefore, in most devices, the right ventricle is the only sensing chamber.

Follow-up of CRT devices includes a 12-lead ECG to assess for Bi-V capture and device interrogation to assess pacing thresholds. In those patients who are deemed nonresponders, echocardiography may be used to optimally time the AV delay based on Doppler mitral valve inflow patterns or Doppler aortic velocity time integral. Generally speaking, interventricular timing (V-V interval), although programmable, is not taken into consideration during CRT programming. Limited studies suggest that AV

programming may lead to a better acute hemodynamic response to CRT in certain patients. The value of VV optimization is of considerable debate. In addition, specialized nonresponder clinics may help troubleshoot device issues, treat arrhythmias, maximize CHF medications, and optimize the AV interval. While such clinics are limited mostly to specialized centers, such clinics have been shown to convert some nonresponders to responders.

XII. LOSS OF CRT. CRT is transiently interrupted in up to 35% of patients and permanently interrupted in 5% at 2 years of follow-up. Fortunately, restoration of CRT can be accomplished via nonsurgical means in the majority of the cases. Pacing parameters, occurrence of atrial arrhythmias, and lead malfunction or dislodgement are common causes of CRT interruption. The goal of continuous pacing during CRT should be reflected in appropriate programming algorithms. Typically, the AV conduction status is what influences continuous delivery of Bi-V pacing. Because the majority of patients who require CRT have an intact AV node, any parameters that allow for preferential native conduction will reduce CRT delivery. Keeping the AV interval as short as possible while maintaining proper ventricular loading is therefore optimal. Atrial arrhythmias are common in advanced HF. Rapid ventricular rate during atrial arrhythmias with rapid AV conduction inactivates Bi-V pacing due to the upper tracking rate limit. Keeping patients in NSR is therefore desirable. Any evidence of lead malfunction or displacement should be dealt with promptly by reintervention. The loss of CRT results in symptomatic deterioration in HF and hospital admission in many instances.

XIII. FUTURE DIRECTIONS. While CRT has emerged as one of the most important advances in the treatment of LVD over the last 15 years, several important questions remain. Despite the myriad of parameters of mechanical dyssynchrony that are available, none has been shown to be a practical and reliable predictor of response. Developing a measure of dyssynchrony that predicts response accurately and can be used across multiple care settings remains a challenge. Whether CRT has a role in patients with a narrow QRS duration remains in question. While the ReTHINQ trial failed to show benefit in this population, a two-dimensional measure of dyssynchrony was used. In the ongoing ECHO-CRT trial, a three-dimensional dyssynchrony measure will be employed, which should shed considerable light on the applicability of CRT in this population. Lastly, the role of CRT in patients without a native or RV-paced LBBB morphology is an area of considerable controversy. Patients with right bundle branch block (RBBB) have early activation of the left ventricle and late activation of the right ventricle, calling into question the role of LV pacing for these patients. Still, most patients with RBBB have a wider QRS duration than would be expected from having a "pure" RBBB alone. This implies additional left-sided delay that may be mitigated by CRT. While retrospective studies have certainly called into question the benefits of CRT in this population, currently, there is no prospective randomized trial to provide a more definitive answer. Patients with nonspecific IVCD are a heterogeneous population, likely with both right- and left-sided delay. In retrospective studies, the response rate of this population is more akin to those with RBBB than LBBB; however, the studies have been small.

XIV. SUMMARY. CRT has emerged as an effective therapy in patients with LVD refractory to CHF medications and a wide QRS duration. Major clinical trials have proven significant morbidity and mortality benefits from CRT first in patients with advanced heart and more recently in those with minimal symptoms. The issue of nonresponse to CRT continues to be a major problem and much ongoing research continues to be dedicated to predicting which patients will respond to this therapy. While many studies have shown some predictive ability of various imaging modalities, none to date has been shown to be a reliable predictor of response that could be utilized across multiple

centers. While the response to CRT in patients with a native LBBB or RV-paced rhythm is well documented, the response in patients with RBBB or a nonspecific IVCD continues to be debated.

CHAPTER 57

Salim H. Ahmed
Thomas D. Callahan
Donald Underwood

Common ECG Patterns

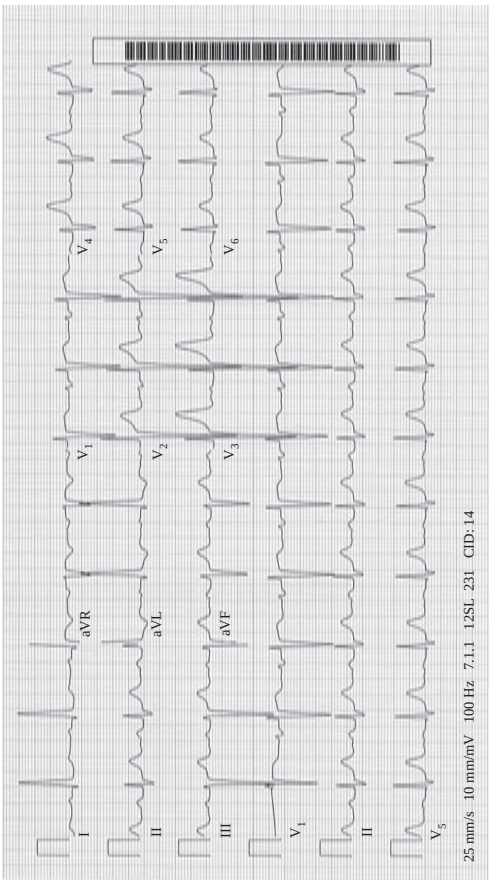

FIGURE 57.1 Left ventricular hypertrophy (LVH).

- Note that the R wave in lead aVL is > 11 mm, and the R wave in lead V_5 or V_6 + S wave in lead V_1 is > 35 mm.
- Left axis deviation is present.
- Left atrial enlargement, which often occurs with LVH, is also present (the terminal negative portion of the P wave in lead V_1 is ≥ 1 mm in depth and ≥ 40 ms in duration, and the P wave is broad in inferior leads).

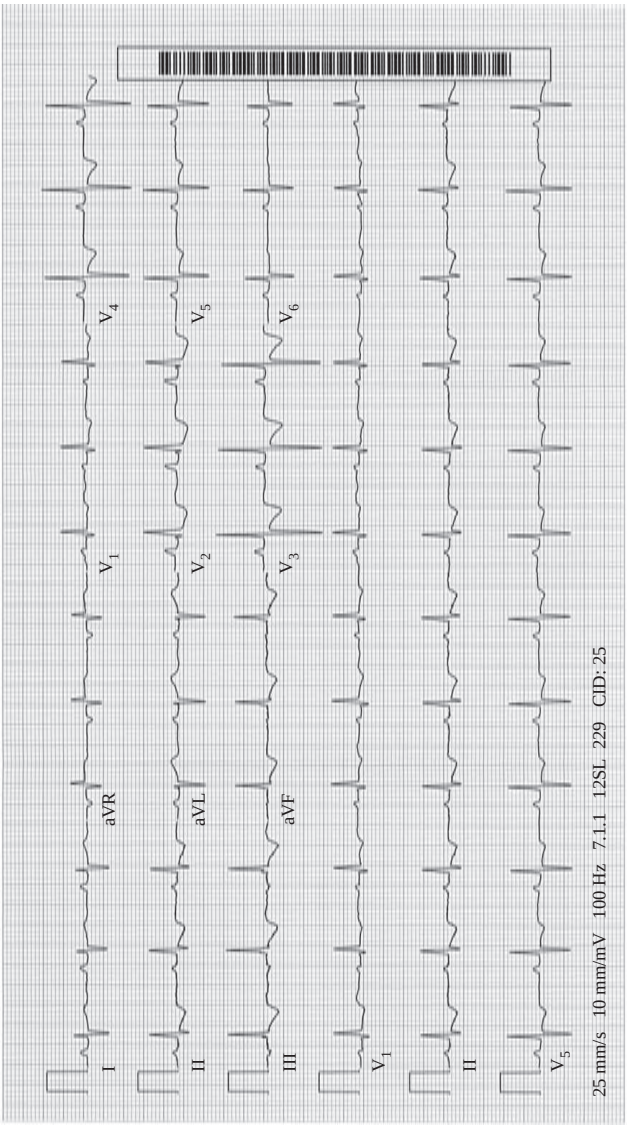

FIGURE 57.2 Right ventricular hypertrophy.

- The R wave in lead V_1 is > 6 mm, and there is right axis deviation (QRS axis > 100°).
- Other criteria include an R/S ratio in lead V_1 > 1 and an R/S ratio in lead V_5 or $V_6 \leq 1$.

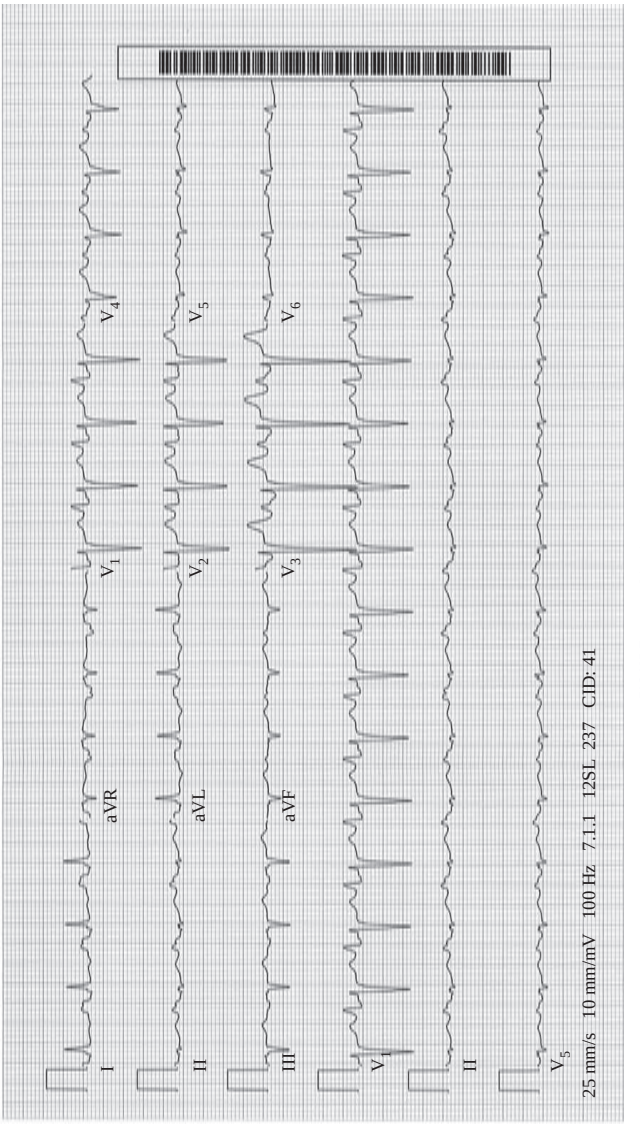

FIGURE 57.3 Biatrial enlargement.

- Left atrial enlargement is indicated by the negative terminal portion of the P wave in lead V_1 and the broad P wave in inferior leads.
- Right atrial enlargement is indicated by the height of the P wave in inferior leads and lead V_1.

Common arrhythmias

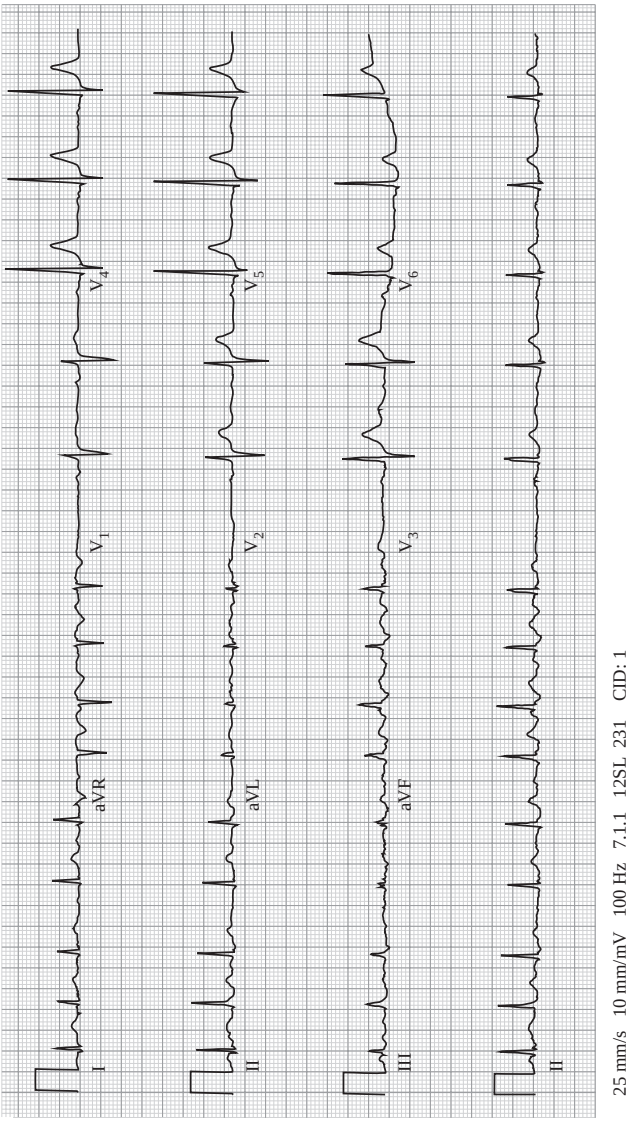

FIGURE 57.4 Atrial fibrillation.

- Irregular activity of the atria causes random oscillation of the baseline, and P waves are absent. The ventricular rate is irregularly irregular.
- The patient spontaneously converted to sinus rhythm midway through the rhythm strip.

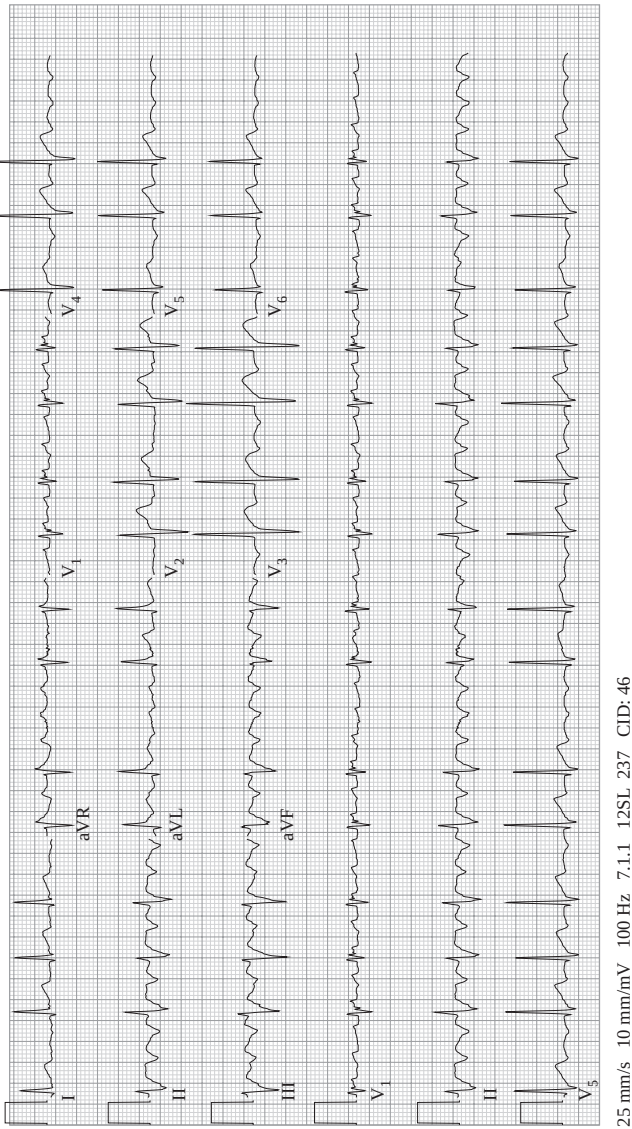

FIGURE 57.5 Typical atrial flutter.

- Flutter waves with a "sawtooth" appearance are present at around 300 beats/min. The waves are negative in inferior leads and positive in lead V_1.

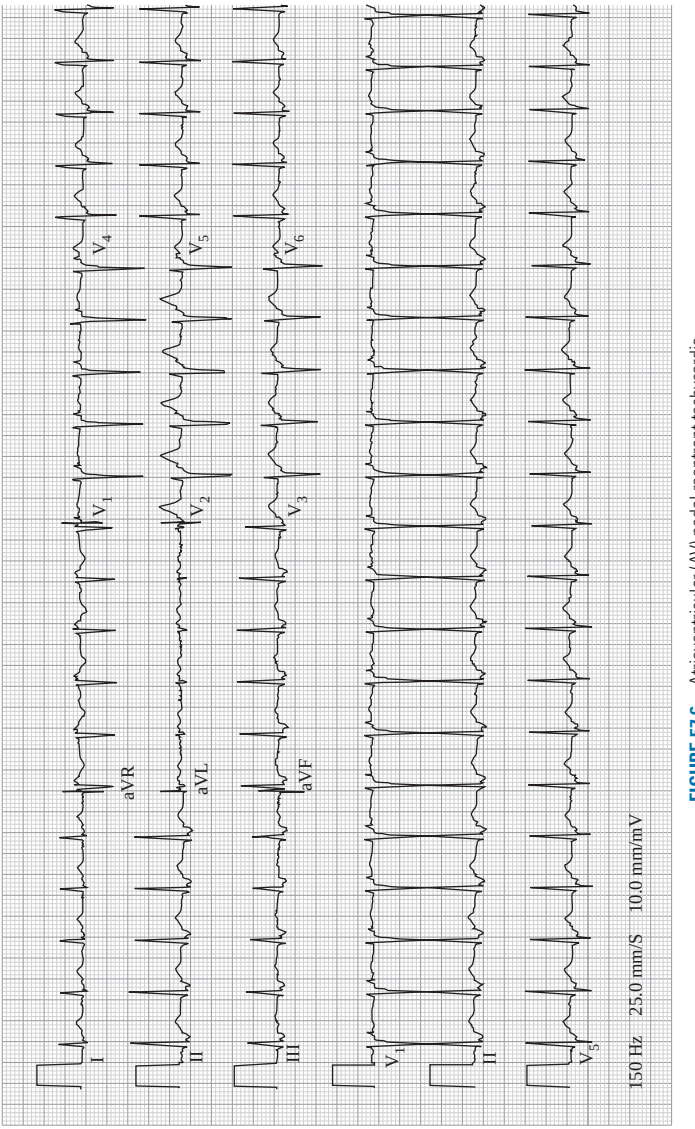

FIGURE 57.6 Atrioventricular (AV) nodal reentrant tachycardia.

- A regular, narrow QRS complex is present.
- A retrograde P wave is seen following the QRS complex in lead V_1 ("pseudo-R′").

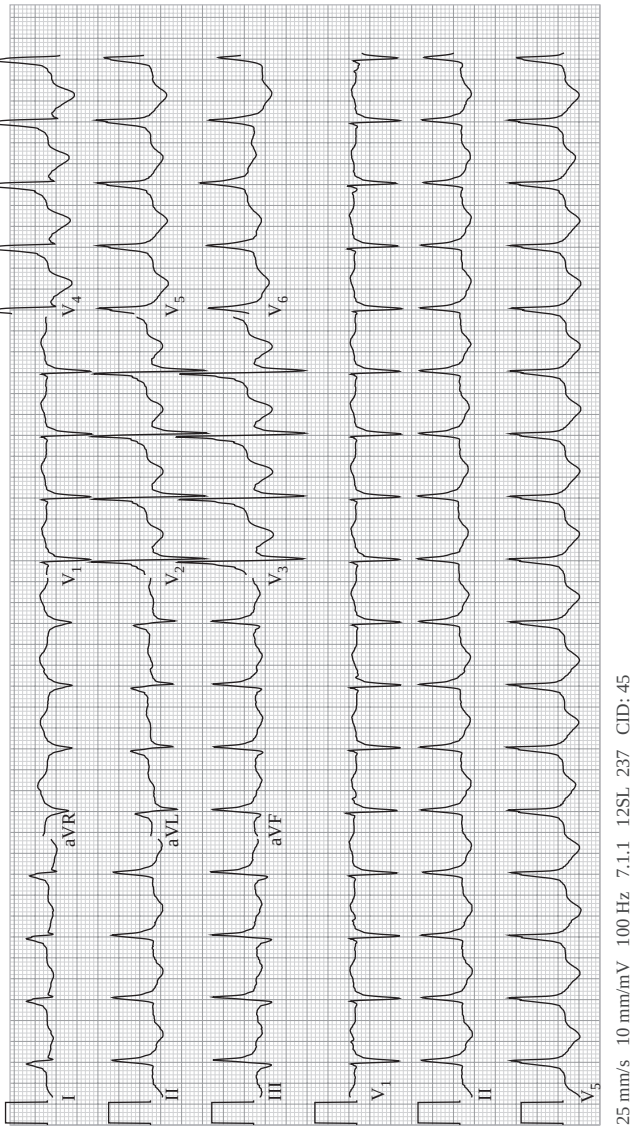

FIGURE 57.7 Ventricular tachycardia.

- A rapid, wide QRS complex is present. P waves are best seen in leads V_1 and II and are clearly dissociated from ventricular activity.

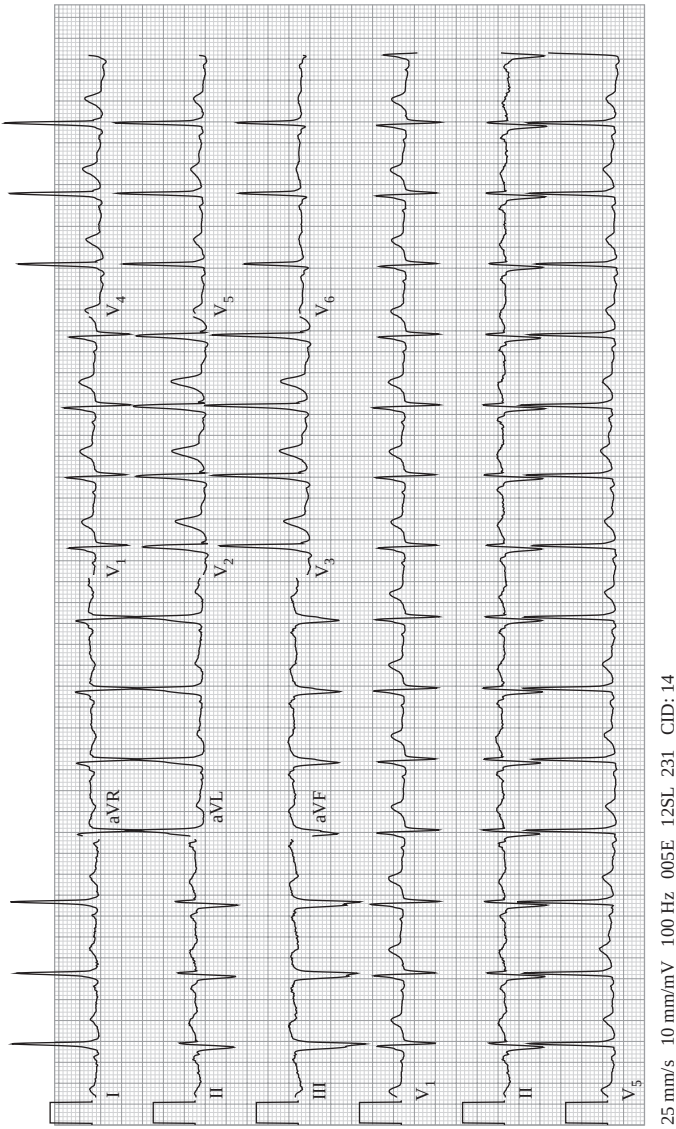

FIGURE 57.8 Wolff-Parkinson-White (WPW) pattern.

- Preexcitation of the ventricle causes a short PR interval and slurring of the initial portion of the QRS complex (delta wave).

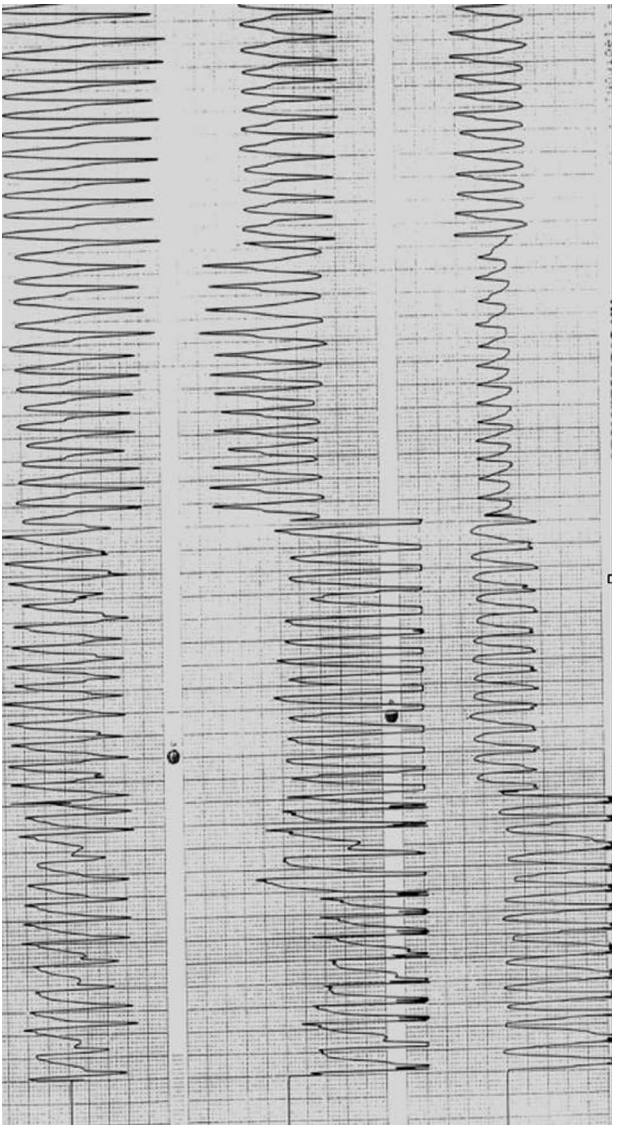

FIGURE 57.9 Atrial fibrillation with WPW.

- If atrial fibrillation develops, conduction to the ventricles can be very rapid. There is a varying degree of fusion between conduction through the AV node and conduction through the bypass tract, causing each beat to have a different morphology.

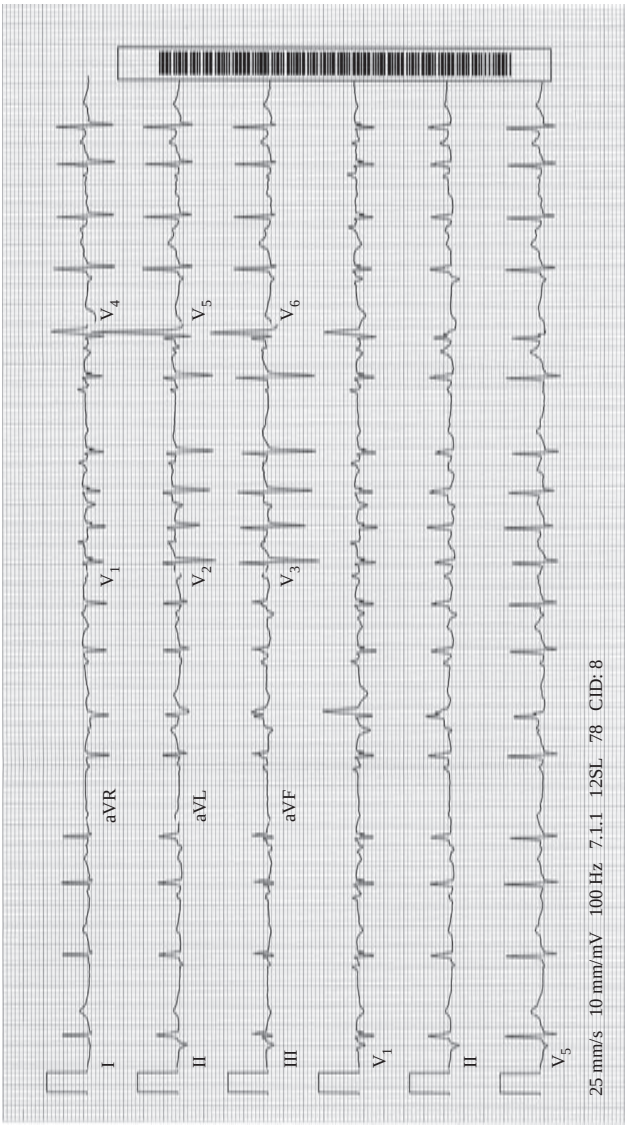

FIGURE 57.10 Multifocal atrial tachycardia.

- The atrial rate is rapid, and multiple P-wave morphologies are present.

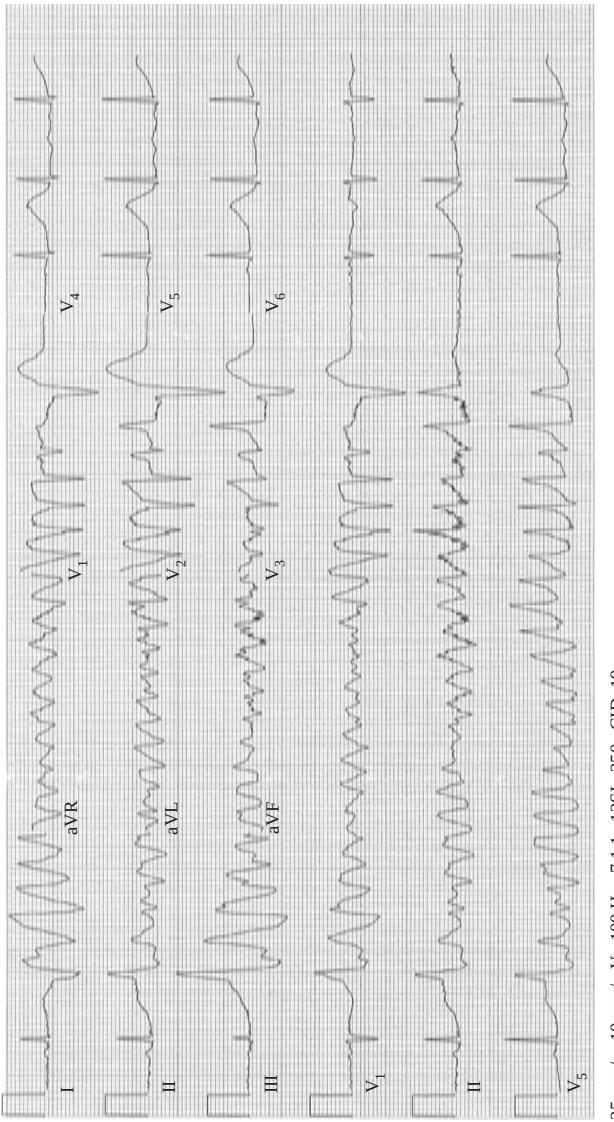

FIGURE 57.11 Torsades.

- A rapid ventricular rhythm with QRS complexes of varying axis ("twisting of the points") is present.

Conduction disease

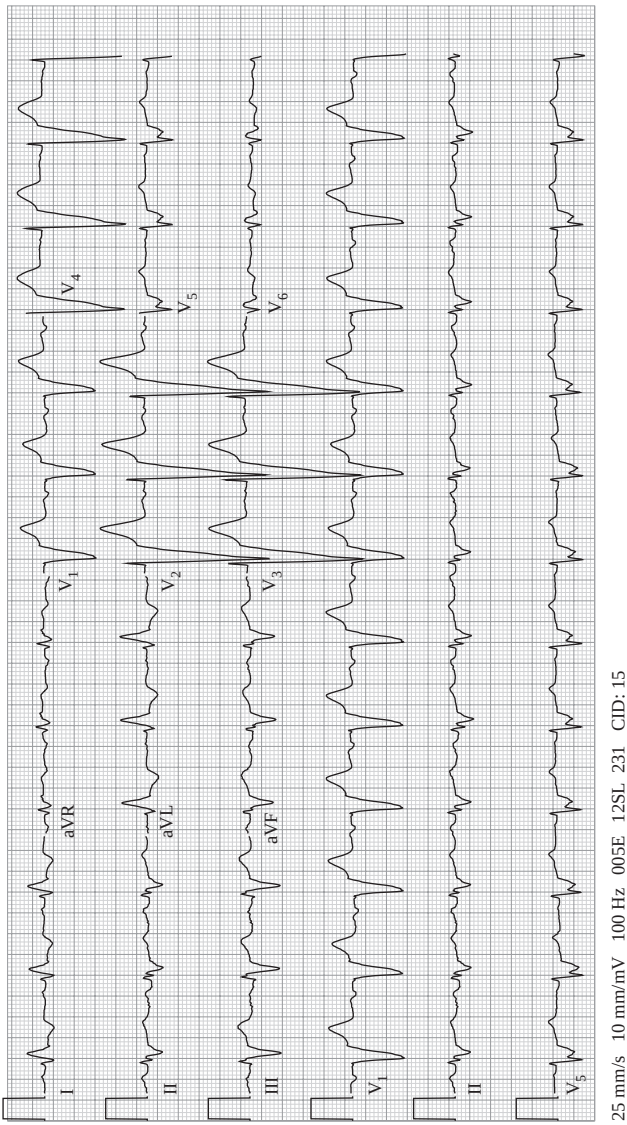

FIGURE 57.12 Left bundle branch block.

- The QRS duration is prolonged (> 120 ms).
- There is a broad R wave in leads I and V_6, representing delayed activation of the left ventricle.
- The right precordial leads have an rS complex.
- There are ST-segment changes in the direction opposite to the major QRS deflection.

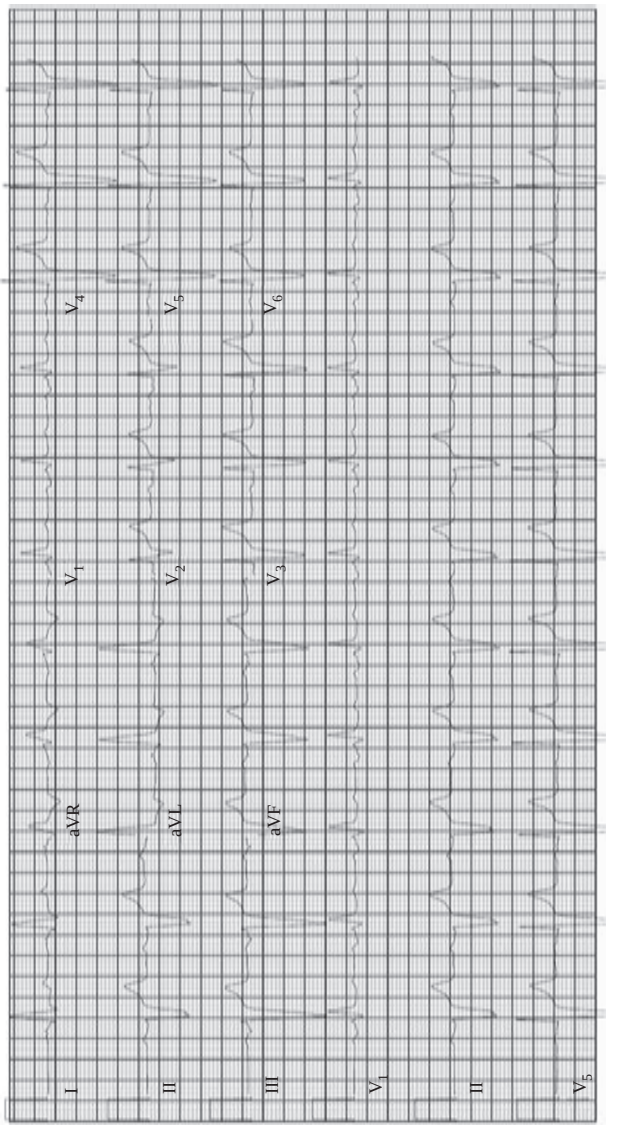

FIGURE 57.13 Right bundle branch block (RBBB) and left anterior fascicular block (LAFB).

- The QRS duration is prolonged beyond 120 ms.
- There is an rsR′ pattern in leads V_1 and V_2, representing delayed activation of the right ventricle.
- Leads I, V_5, and V_6 have a wide, slurred S wave.
- LAFB is indicated by the presence of left axis deviation without another cause (inferior infarction, LVH, chronic obstructive pulmonary disease, and ostium primum atrial septal defect) and the rS complex in inferior leads.

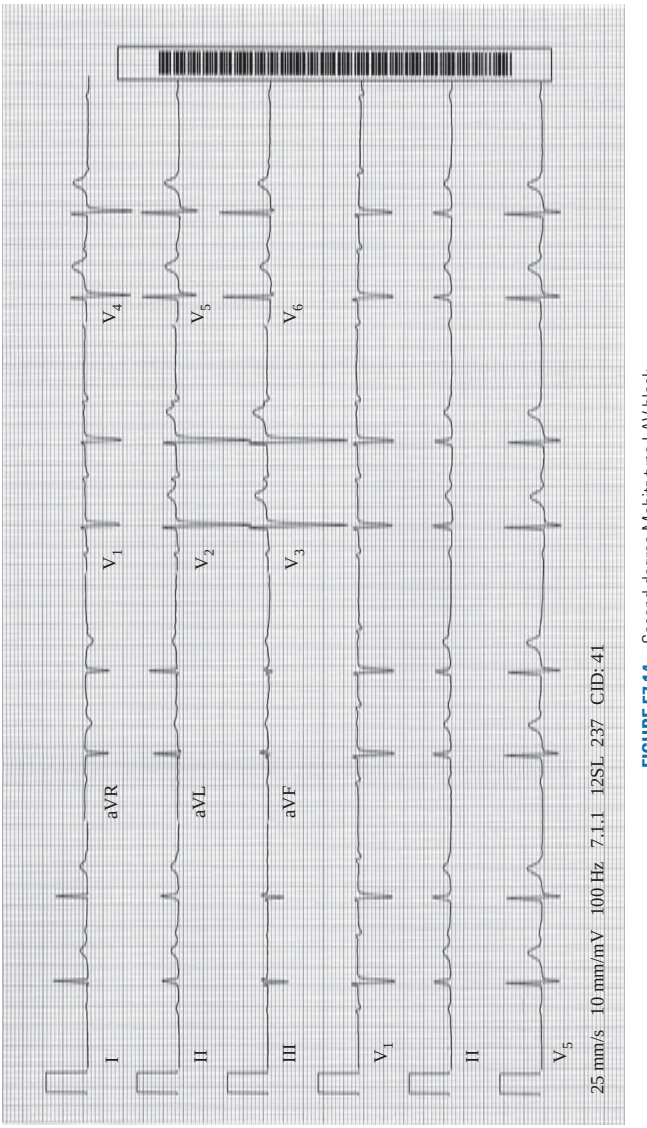

FIGURE 57.14 Second-degree Mobitz type I AV block.

- There is progressive prolongation of the PR interval until a P wave blocks.

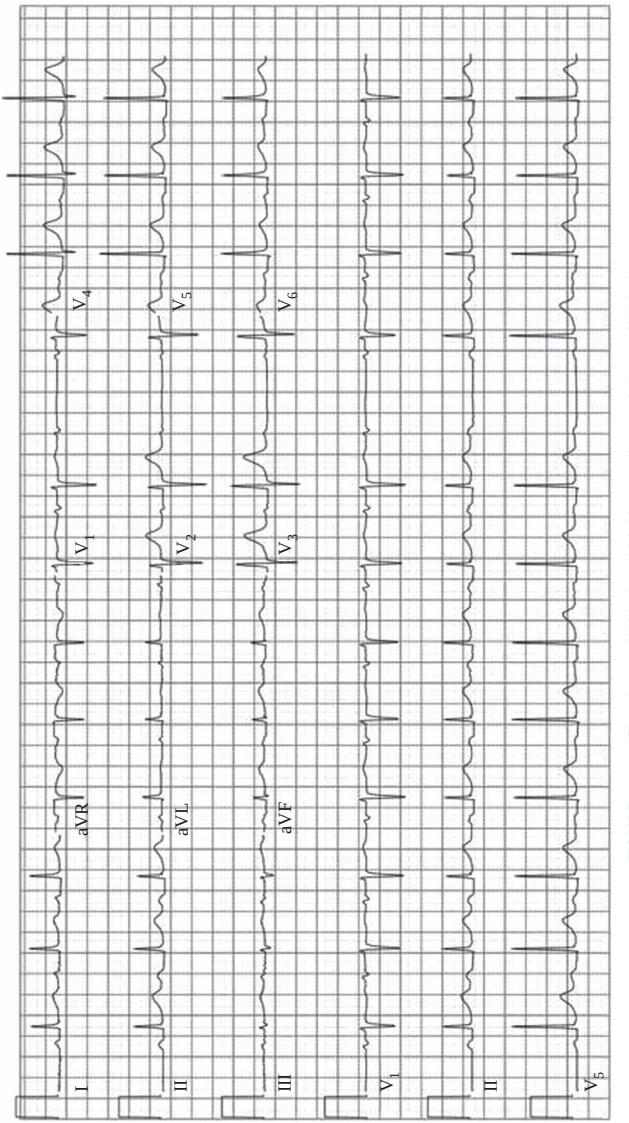

FIGURE 57.15 First-degree AV block and Mobitz type II second-degree AV block.

- The PR interval is more than 200 ms, indicating first-degree AV block.
- A P wave intermittently blocks. There is no lengthening of the PR interval prior to the dropped beat.

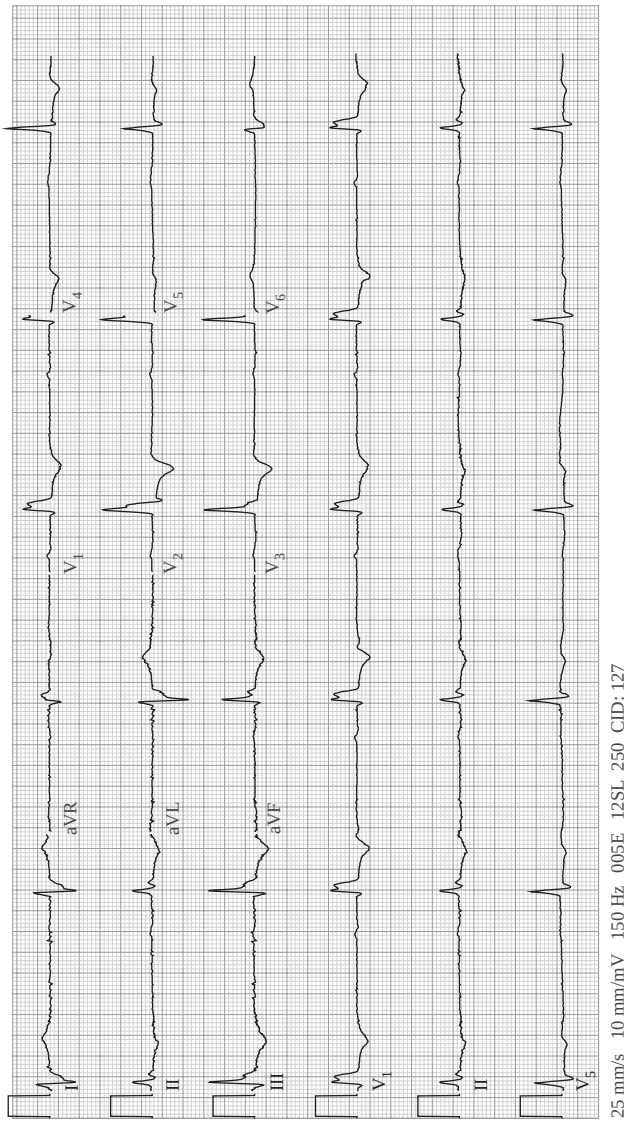

FIGURE 57.16 Complete heart block.

- P waves are not conducted to the ventricles, leading to atrial and ventricular rhythms that are independent of each other.
- The P-P and R-R intervals are constant, but the PR interval varies.

Metabolic disturbances

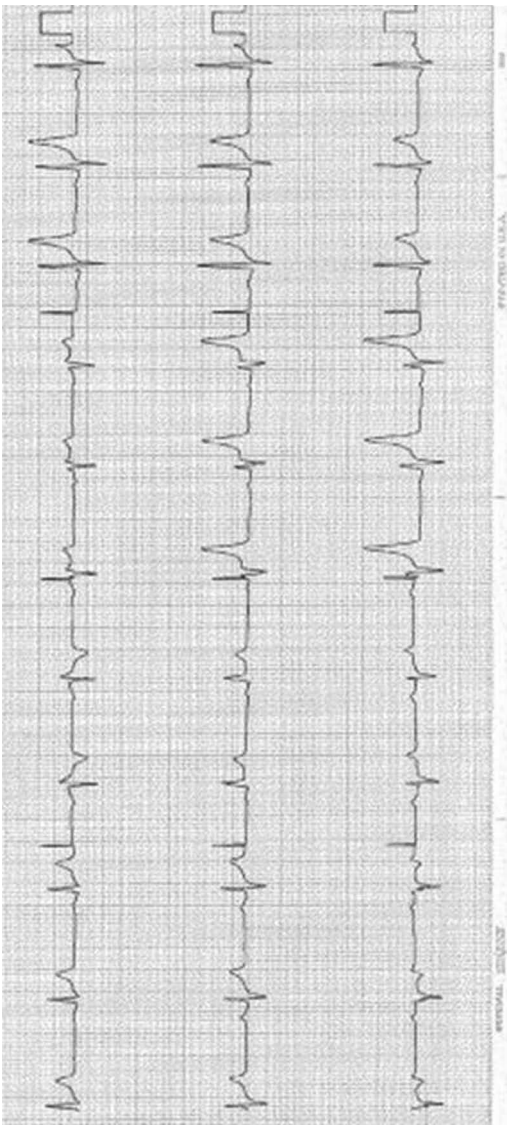

FIGURE 57.17 Hyperkalemia.

- Tall, peaked T waves are present.
- The QT interval is short.

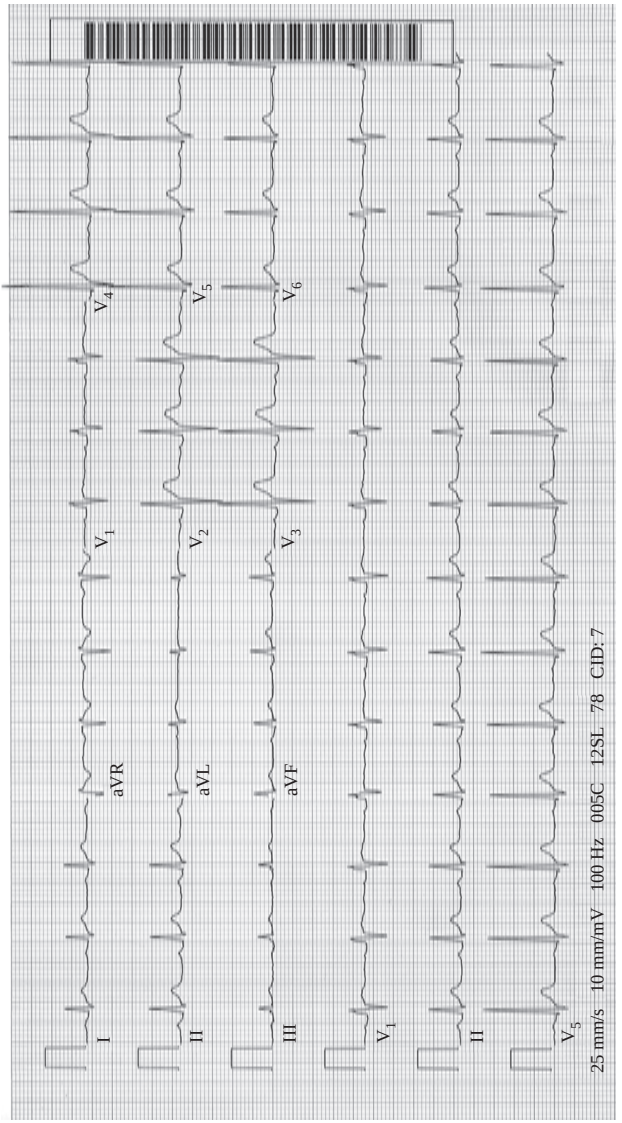

FIGURE 57.18 Hypercalcemia. Reprinted from Bashian GG, Rimmerman CM. Twelve-lead electrocardiography. In: Griffin BP, Rimmerman CM, Topol EJ, eds. *The Cleveland Clinic Cardiology Board Review.* Philadelphia, PA: Lippincott Williams & Wilkins; 2007:552.

- The QT interval is short.

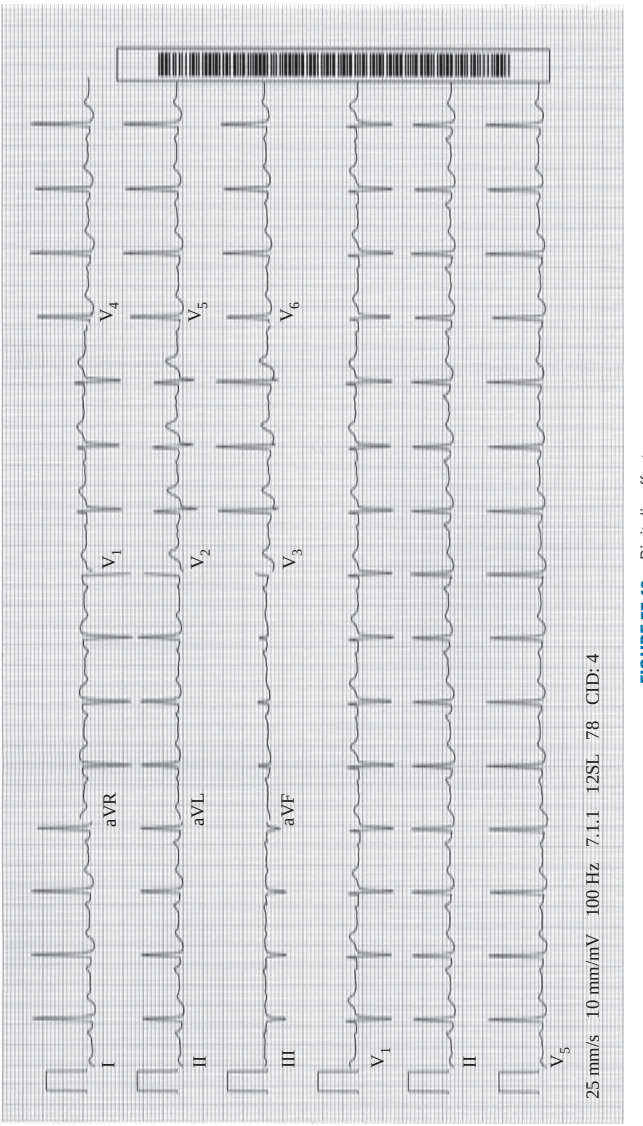

FIGURE 57.19 Digitalis effect.

- The ST segments sag downward and have upward concavity.
- The PR lengthens and the QT is short.

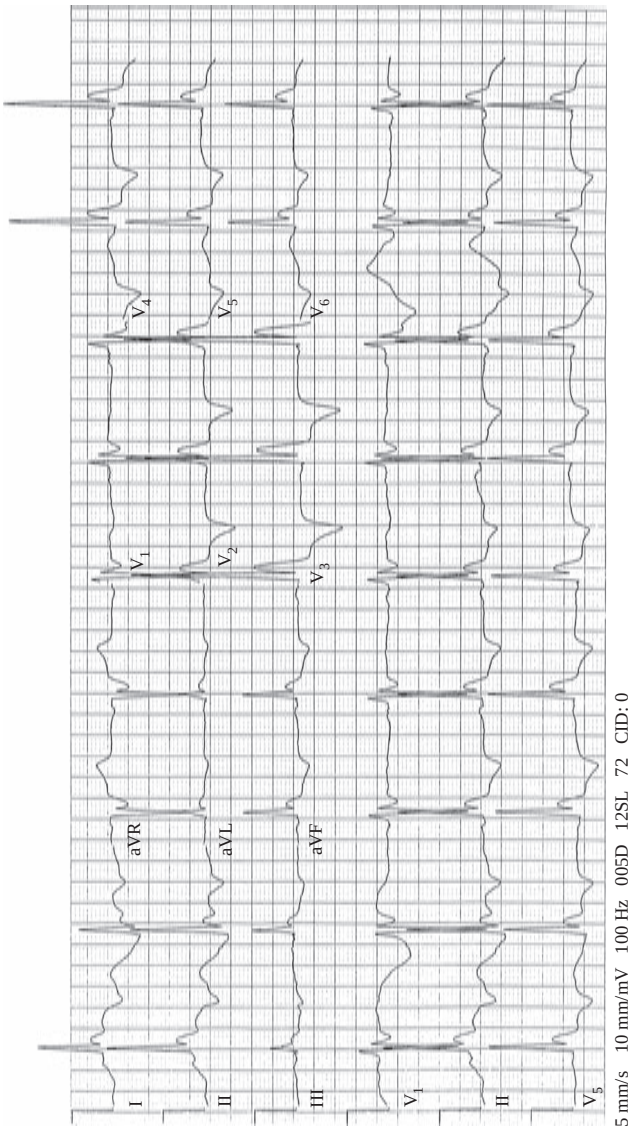

FIGURE 57.20 Hypothermia. Reprinted from Bashian GG, Rimmerman CM. Twelve-lead electrocardiography. In: Griffin BP, Rimmerman CM, Topol EJ, eds. *The Cleveland Clinic Cardiology Board Review.* Philadelphia, PA: Lippincott Williams & Wilkins; 2007:588.

- An Osborn or J wave is present at the terminal portion of the QRS complex.
- The QRS interval is prolonged, and there is sinus bradycardia in this example. The PR and QT intervals may also be prolonged.

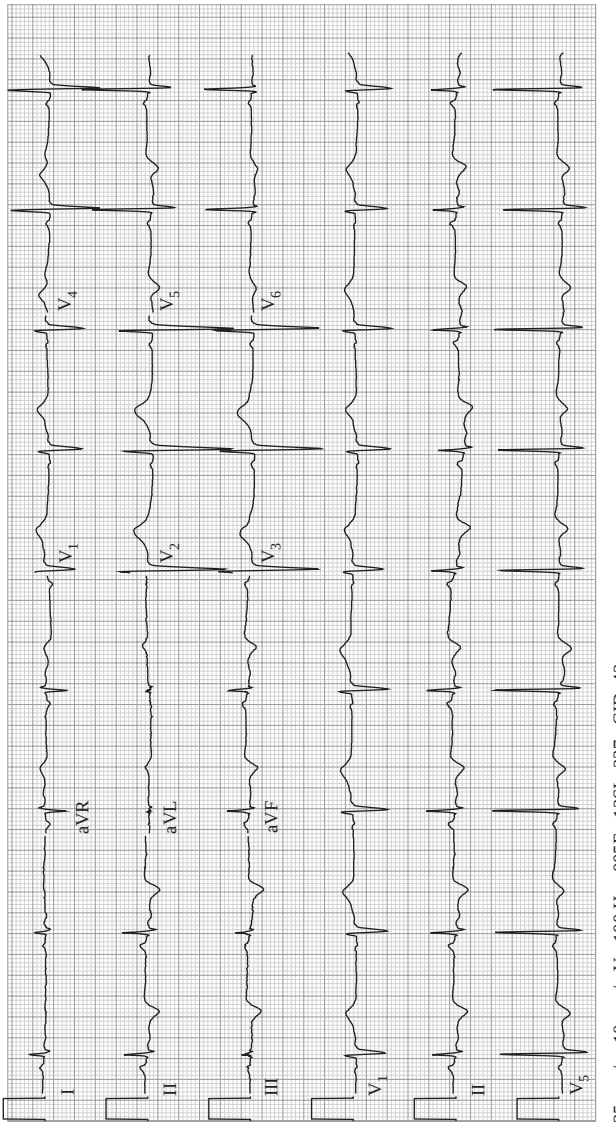

FIGURE 57.21 Long QT syndrome.

- The QTc interval is ≥ 440 ms.
- Congenital long QT type I was genetically confirmed in this patient.

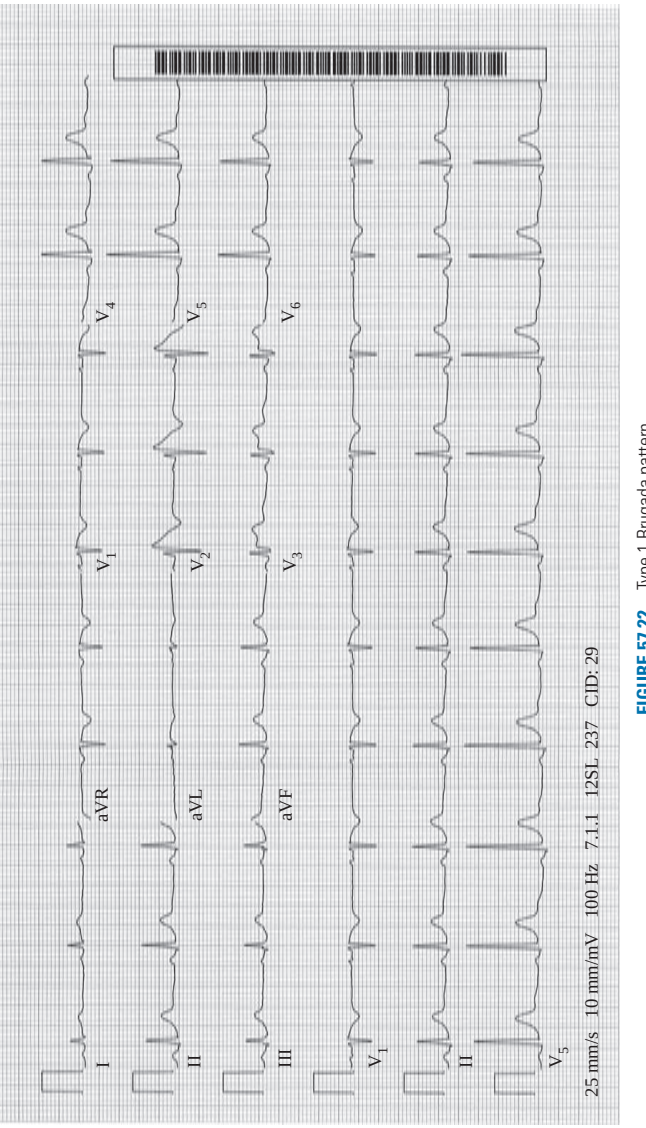

FIGURE 57.22 Type 1 Brugada pattern.

- There is an incomplete RBBB pattern with ST elevation in leads V_1 and V_2.

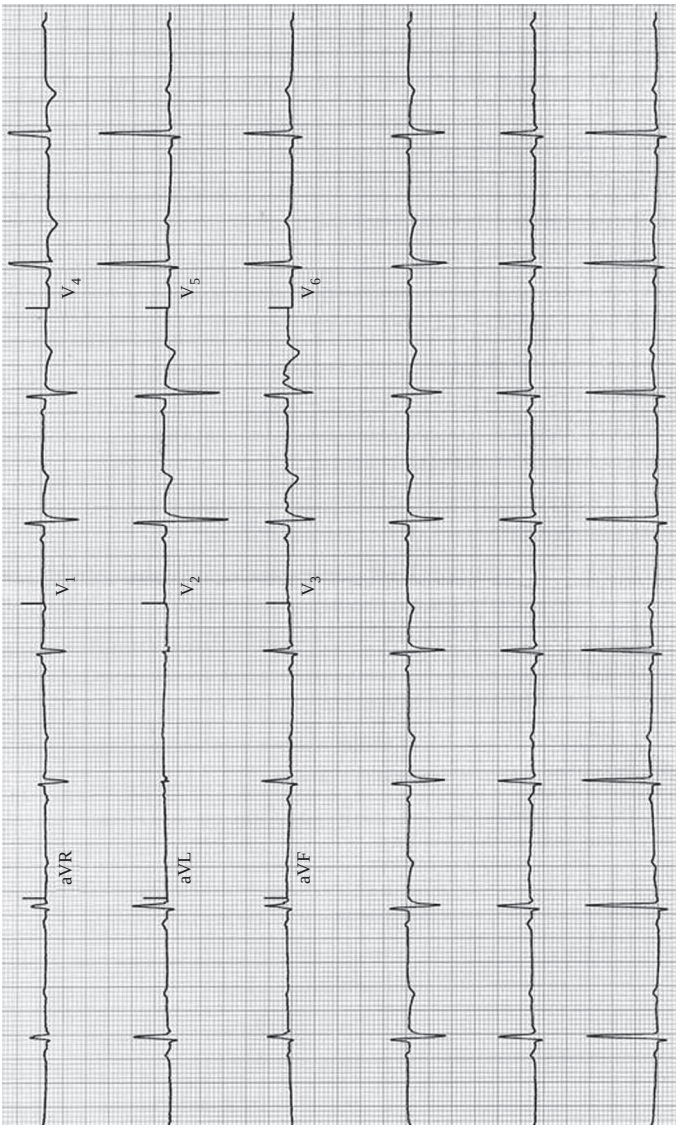

FIGURE 57.23 Arrhythmogenic right ventricular cardiomyopathy.

- An epsilon wave is present after the QRS complex in lead V_3. The epsilon wave may also be seen in leads V_2 and V_3.
- T-wave inversion in the anteroseptal leads is present.

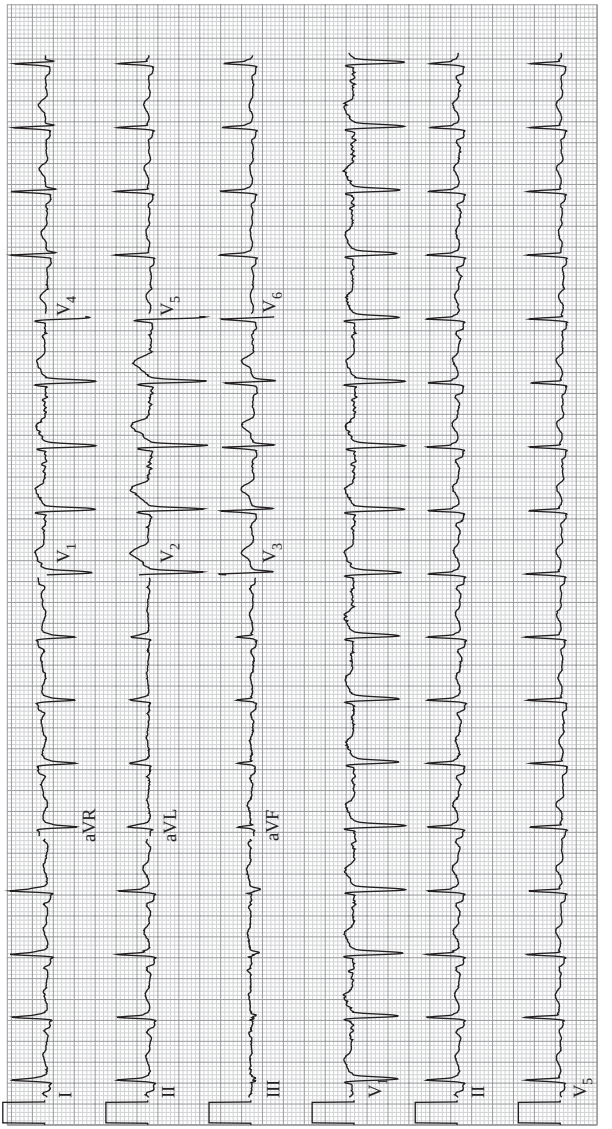

FIGURE 57.24 Pericarditis.

- There is diffuse, upwardly concave ST-segment elevation.
- The PR segment is depressed.

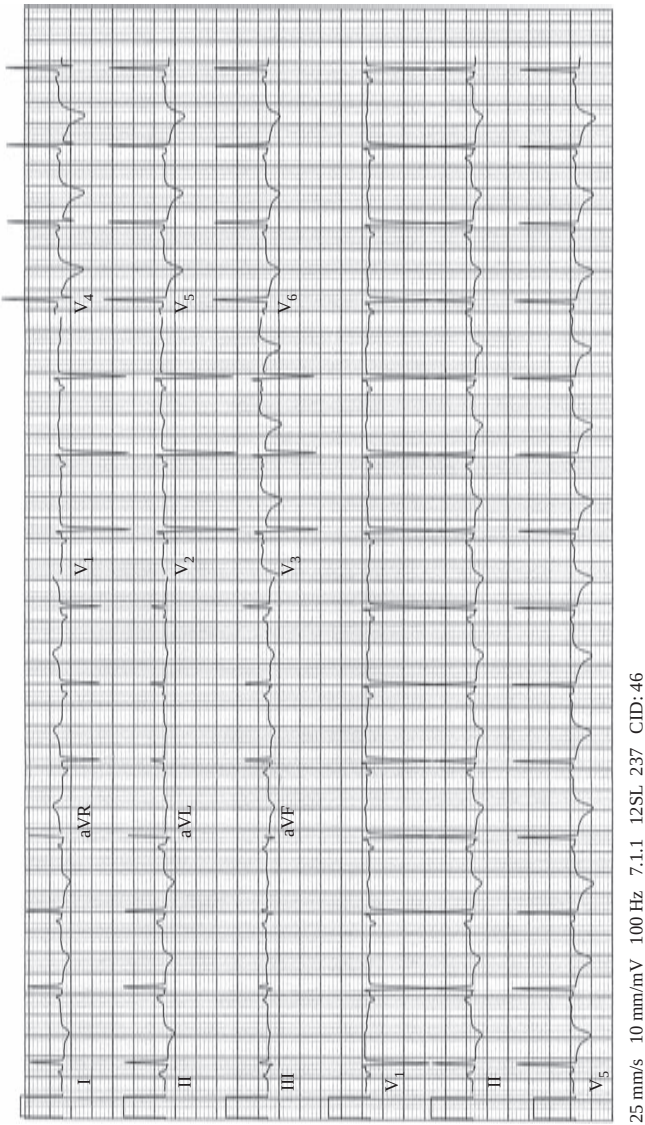

FIGURE 57.25 Takotsubo cardiomyopathy.

- Diffuse ST depression and T-wave inversion are present in this example. ST elevation may also be present.

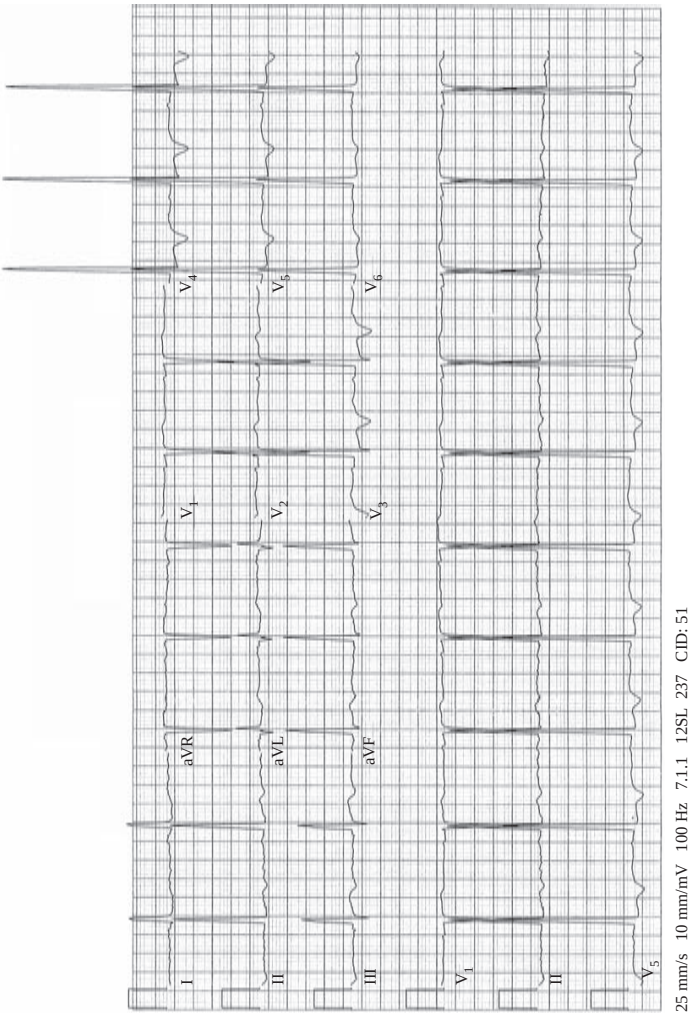

FIGURE 57.26 Apical variant of hypertrophic cardiomyopathy.

- Voltage in the precordial leads is increased and there is anterolateral T-wave inversion.

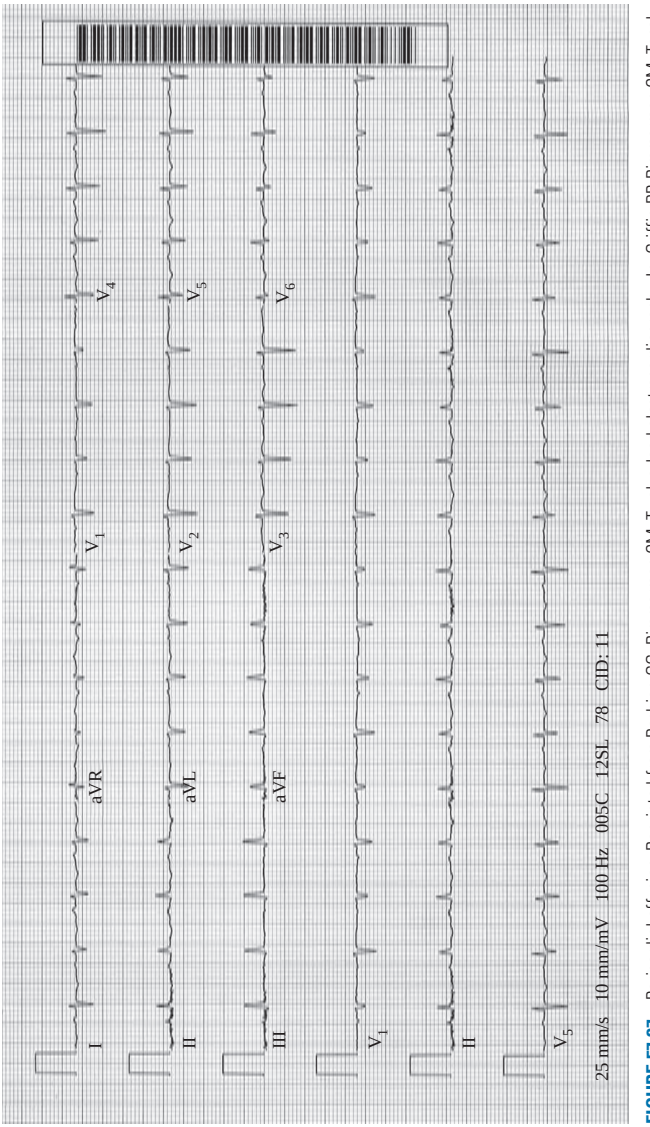

FIGURE 57.27 Pericardial effusion. Reprinted from Bashian GG, Rimmerman CM. Twelve-lead electrocardiography. In: Griffin BP, Rimmerman CM, Topol EJ, eds. *The Cleveland Clinic Cardiology Board Review.* Philadelphia, PA: Lippincott Williams & Wilkins; 2007:573.

- Low voltage and electrical alternans are present. This is most apparent in lead V_1.

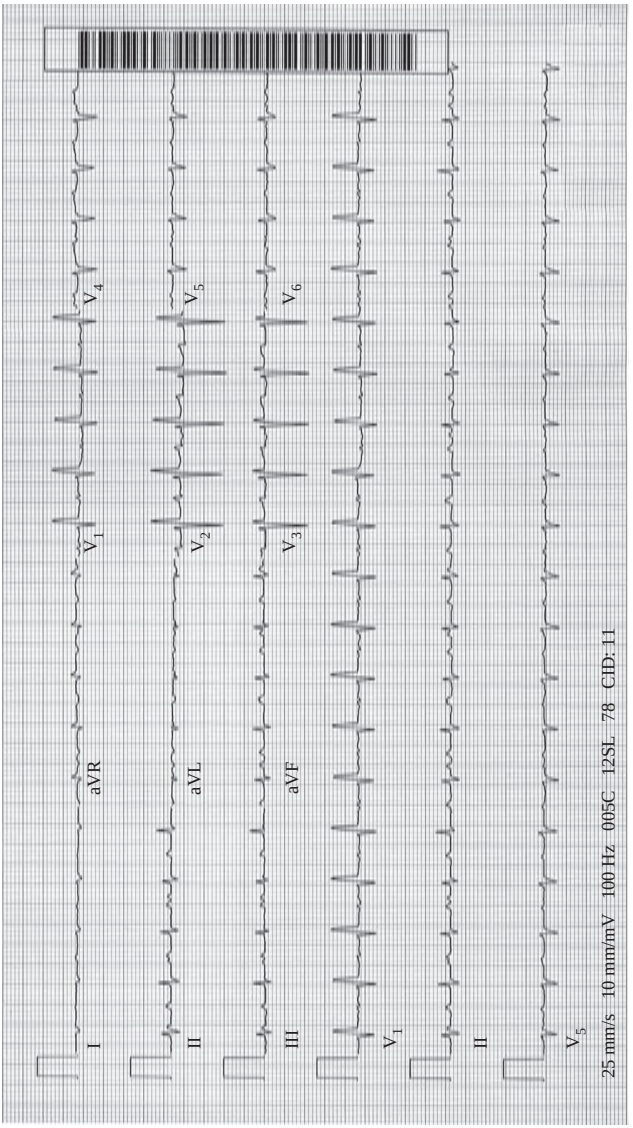

FIGURE 57.28 Cardiac transplant. Reprinted from Bashian GG, Rimmerman CM. Twelve-lead electrocardiography. In: Griffin BP, Rimmerman CM, Topol EJ, eds. *The Cleveland Clinic Cardiology Board Review*. Philadelphia, PA: Lippincott Williams & Wilkins; 2007:541.

- Two sets of P waves, one from the native right atrium and one from the donor heart, are visible.
- Incomplete RBBB and first-degree AV block are also present.

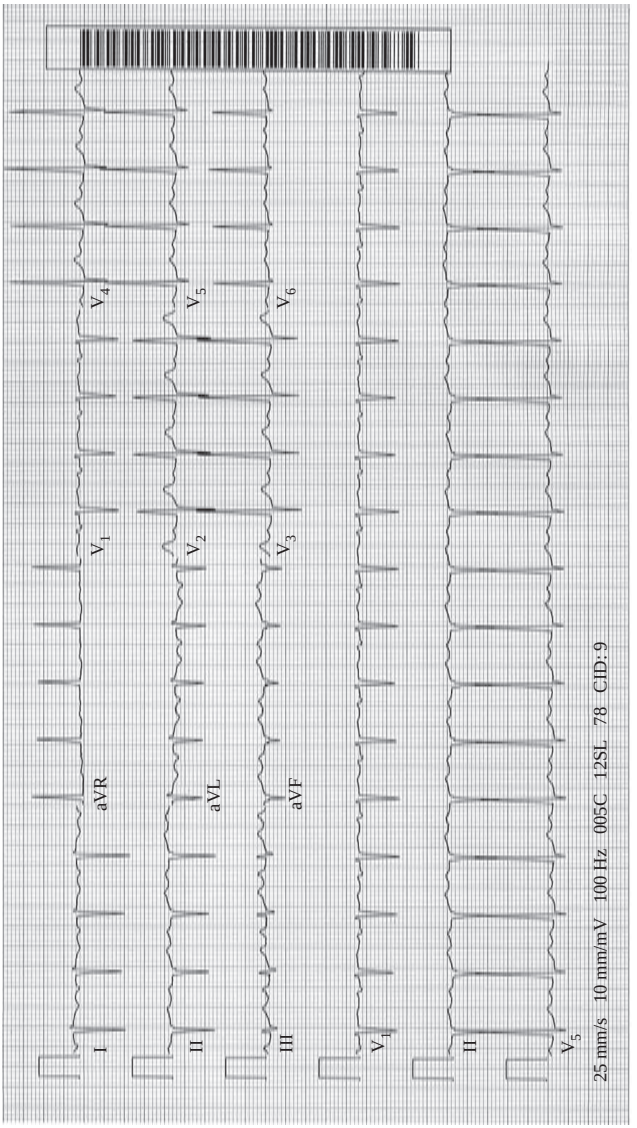

FIGURE 57.29 Limb lead reversal. Reprinted from Bashian GG, Rimmerman CM. Twelve-lead electrocardiography. In: Griffin BP, Rimmerman CM, Topol EJ, eds. *The Cleveland Clinic Cardiology Board Review.* Philadelphia, PA: Lippincott Williams & Wilkins; 2007:555.

- The QRS complex is negative in lead I, with normal R-wave progression.
- The P wave is negative in leads I and aVL.

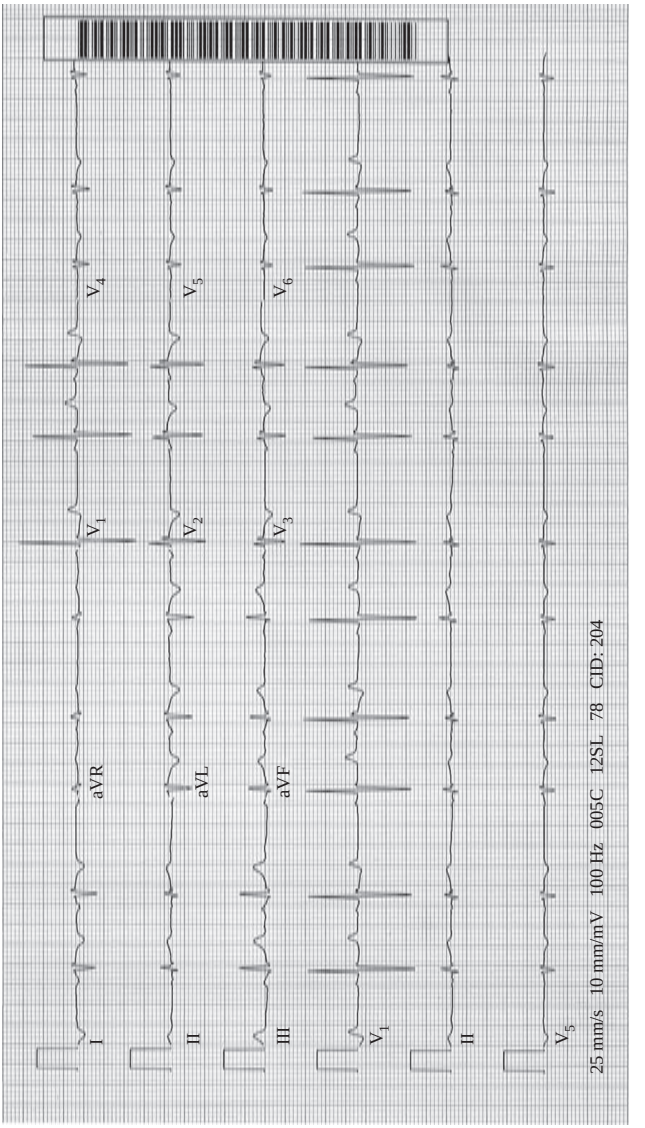

FIGURE 57.30 Dextrocardia. Reprinted from Bashian GG, Rimmerman CM. Twelve-lead electrocardiography. In: Griffin BP, Rimmerman CM, Topol EJ, eds. *The Cleveland Clinic Cardiology Board Review.* Philadelphia, PA: Lippincott Williams & Wilkins; 2007:556.

- The QRS complex is negative in lead I, with R-wave regression across the precordium.
- The P wave is negative in leads I and aVL.
- A premature atrial complex is also present.

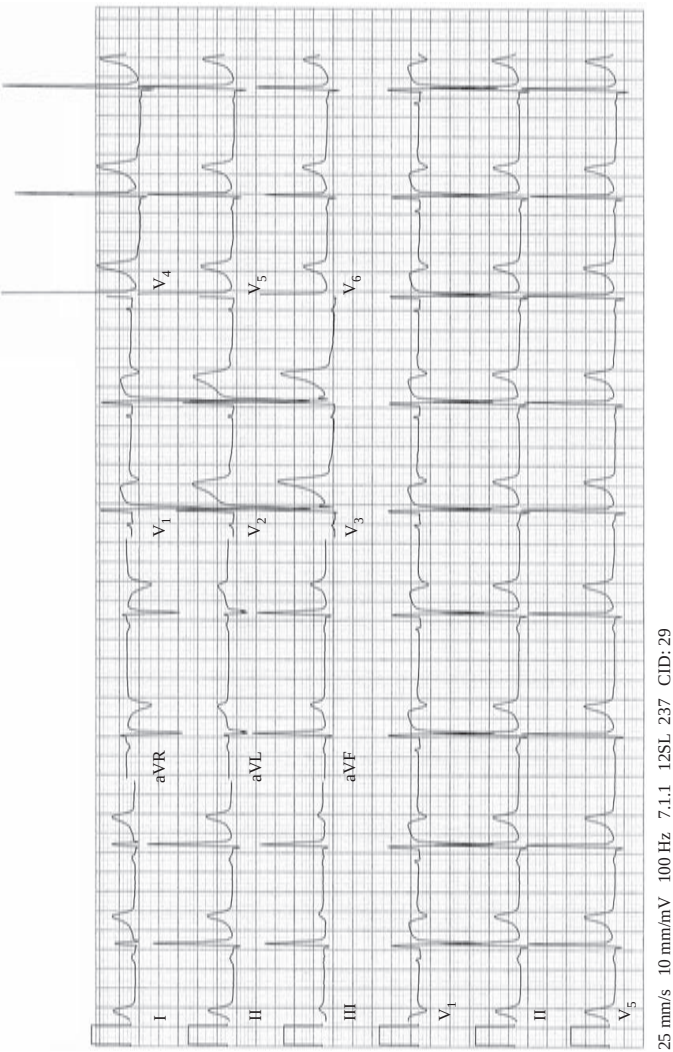

FIGURE 57.31 Early repolarization.

- This electrocardiogram from a young, well-trained athlete shows J-point elevation, concave ST-segment elevation, and large symmetrical upright T waves.
- There is a notch in the downstroke of the R wave.

CHAPTER 58

Temporary Cardiac Pacing

I. INDICATIONS

A. Acute hemodynamically significant bradycardia or asystole. Temporary pacing is indicated in patients with acute hemodynamically significant bradycardia or asystole. Reversible causes such as digitalis toxicity, antiarrhythmic agents, and electrolyte disturbances such as hyperkalemia should be determined and reversed.

B. Termination of tachycardias (overdrive pacing). Temporary pacing is indicated for overdrive pacing and termination of atrial flutter (type I with long excitable gap) or supraventricular tachycardia due to a reentrant mechanism.

C. Bridge to permanent pacing. Temporary pacing may be used as a bridge to permanent pacing in patients with complete heart block, high-grade second-degree block, severe sinus node dysfunction, and asystole. Generally, temporary pacing in this setting is for patients with an acute illness (endocarditis and systemic infection elsewhere) that delays permanent pacemaker placement.

D. Ventricular tachycardia. Temporary pacing is indicated in patients with bradycardia-dependent ventricular tachycardia and recurrent tachyarrhythmias secondary to long QT syndrome or pause-dependent ventricular tachycardia. Monomorphic ventricular tachycardia can be terminated with antitachycardia pacing through a ventricular temporary wire by pacing at a rate faster than the tachycardia. This involves pacing the chamber in which the reentrant circuit exists. Overdrive pacing is initiated at 10 to 15 beats per minute (bpm) faster than the tachycardia. Pacing is done for several captured beats (up to 10 to 15 seconds) and then abruptly stopped. If tachycardia persists, the pacing rate is sequentially increased by 10 bpm and pacing repeated. The major potential complication of this technique is conversion to a faster or unstable rhythm. The advantage is that post-tachycardia pauses can be managed with pacing if necessary, and direct current cardioversion may be avoided.

E. Acute myocardial infarction. Indications for temporary pacing in this setting include development of a new bifascicular block (right bundle branch block [RBBB] with either left-axis [left anterior hemiblock] or right-axis deviation [left posterior hemiblock]), new left bundle branch block (LBBB) with first-degree atrioventricular (AV) block, alternating LBBB and RBBB, Mobitz type II block, and complete heart block. Patients with right ventricular infarction and loss of AV synchrony may benefit from AV sequential pacing.

F. Condition where there is a chance of recovery. In certain forms of myocarditis with heart block, such as Lyme disease, or post cardiac surgery, temporary pacing can be used because there is a significant chance of recovery of conduction.

G. Acute aortic regurgitation. Pacing to increase heart rate in patients with acute aortic regurgitation who have bradycardia and elevated left ventricular end-diastolic pressure can reduce diastolic filling time and improve hemodynamics.

H. Prophylactic. Prophylactic temporary pacing is considered in the following settings: (a) in patients undergoing right heart catheterization and/or myocardial biopsy in the

setting of an LBBB, (b) with complex intervention to the right coronary artery as this supplies the AV node in 90% of individuals, (c) cardioversion in patients with the sick sinus syndrome, although generally the use of transcutaneous pacing back up is used instead, (d) or new 1st degree AV block with acute endocarditis (especially of the aortic valve). Patients who are undergoing alcohol septal ablation for hypertrophic cardiomyopathy receive prophylactic transvenous pacers, given the significant risk of complete heart block during the procedure. Patients who are undergoing balloon aortic valvuloplasty and percutaneous aortic valve replacement have a temporary pacemaker placed for overdrive pacing during balloon inflation and valve implantation.

I. Electrophysiologic studies. Temporary atrial, coronary sinus, and ventricular pacemakers are frequently used for electrophysiologic studies.

J. Ischemic evaluation. Ischemic evaluation is occasionally performed via rapid atrial pacing.

II. PACING MODES

A. Transcutaneous pacing. Transcutaneous ventricular pacing involves placement of large-surface-area, high-impedance electrodes (Zoll pads) on the anterior (over lead V_3 or the palpable cardiac apex) and posterior chest walls (inferior aspect of the scapula, to the left or right of the spine). It usually requires long pulse widths (20 to 40 milliseconds) and high outputs of up to 100 to 200 mA. Transcutaneous pacing may be useful when transvenous pacing is contraindicated and in code situations. It avoids the complications associated with transvenous pacers such as pneumothorax, right ventricular perforation, infection, bleeding, and venous thrombosis. Failure to capture and severe patient discomfort are common.

B. Transesophageal or transgastric pacing. This technique uses a flexible electrode on the tip of a catheter that is advanced down the esophagus to a position just behind the left atrium and is usually successful in achieving atrial pacing. The electrode can also be advanced to the fundus of the stomach to pace the ventricle through the diaphragm. However, ventricular pacing is difficult to achieve consistently and without intolerable pain to the patient.

C. Epicardial pacing. Temporary epicardial pacing wires are typically placed at the time of valve surgery, given that there is a 6% rate of need for pacemaker prior to discharge in this population, as compared to 0.8% in the setting of coronary artery bypass grafting. Longer cross-clamp time, multiple valve surgical procedure, absence of preoperative sinus rhythm, and reoperation are all predictors of the need for pacemaker implantation in the valvular surgery population. The electrodes are typically removed with gentle traction when they are no longer needed or no longer functional.

D. Transvenous pacing

1. Relative contraindications
   - **a.** Poor vascular access
   - **b.** Bleeding disorders or anticoagulant therapy. If the international normalized ratio is >1.8 and platelets are < 50,000, then these conditions should be corrected prior to placement of a transvenous pacer if possible.
2. Patient preparation
   - **a.** Informed consent should be obtained for the procedure. However, if the patient is hemodynamically unstable because of a cardiac arrhythmia that could be improved with a pacemaker, this procedure is indicated emergently.
   - **b.** If the procedure is elective, peripheral intravenous access should be obtained before the start of the procedure.
   - **c.** The procedure should be performed in a monitored setting that is equipped for cardiopulmonary resuscitation and with fluoroscopy being available.
3. **Technique**
   - **a. Lead choice.** There is some evidence that active fixation leads allow for greater pacemaker stability and fewer complications than passive fixation

leads. However, active fixation leads can be technically more challenging to place.

b. Sites. The preferred site for pacemaker insertion is the right internal jugular vein. The subclavian vein, femoral vein, and external jugular vein can also be used. However, if a permanent pacemaker will eventually be inserted, the subclavian vein site ipsilateral to the planned permanent pacemaker site should be avoided, if possible. The easiest access in the catheterization laboratory is usually the femoral vein.

c. Position. The patient should be placed supine in bed. The patient may be placed in the Trendelenburg position for internal jugular and subclavian vein cannulation.

d. Placement

(1) Ventricular pacing. A venous sheath is inserted into one of the central veins, and pacing catheters are used. When using passive fixation leads, the pacing catheter is advanced through the venous sheath under fluoroscopic guidance (usually 20° to 30° left anterior oblique projection). The catheter is advanced to the tricuspid valve and turned either clockwise or counterclockwise to direct the tip anteriorly. An attempt is made to cross the valve directly. If unsuccessful, gentle pressure is applied and the catheter is torqued, allowing the middle portion to prolapse across the valve into the right ventricle. If the tricuspid valve is difficult to traverse, it may be possible to enter the right ventricle by looping the tip of the catheter against the lateral atrial wall and then rotating the loop medially (counterclockwise) toward the septum. Another option is to reshape the catheter manually, increasing the tip bend before attempting to traverse the tricuspid valve. Once the catheter has entered the right ventricle, it is rotated so that the tip points inferiorly to the apex with minimal movement in systole. The lead can also be advanced into the right ventricular outflow tract, then slowly pulled back until it drops, and then advanced into the apex as it drops. Some degree of buckling is acceptable; however, excessive buckling increases the risk of perforation. Ideally, the pacemaker tip should be near the apex of the right ventricle. The ideal catheter placement site is on the diaphragmatic surface or "floor" of the right ventricle anywhere between its midpoint and its apex. The floor of the more proximal ventricle is a second choice; the true apex is not a good choice for placement of the catheter tip. The paced electrocardiogram from this location usually shows an LBBB pattern with left-axis deviation. Ventricular pacing can also be done with the tip in the right ventricular outflow tract if the catheter cannot be placed on the floor of the right ventricle in a stable position. The pacer tip is considerably less stable at this site compared with the right ventricle floor and is more likely to be displaced; however, this is a very good position for a screw-in temporary pacing wire. Pacing from this location will show an LBBB pattern with an inferior axis. Use of a balloon-tipped temporary pacing electrode can aid in the advancement of the electrode into the proper position. In addition, echocardiographic guidance can be used to help guide lead placement in situations where fluoroscopy is not available or advisable (e.g., pregnant women).

(2) Atrial pacing. The right atrium is the easiest chamber to reach and pace, but the most stable position is usually found in the right atrial appendage. For atrial pacing, a J-tipped atrial pacing catheter is used. Alternatively, a temporary screw-in lead can be placed in a stable position with good pacing and sensing thresholds. The atrial appendage is directed anteriorly above the tricuspid annulus, and multiple planes are

frequently helpful in verifying the location. (The catheter appears as a "J" in the left anterior oblique projection or as an "L" in the right anterior oblique projection.)

(3) Both atrial and ventricular pacing may be performed by placing the catheter in the coronary sinus. The coronary sinus in its proximal portion courses along the left atrium. Ventricular pacing may be achieved by positioning the catheter in a cardiac vein off the coronary sinus. The threshold in the coronary sinus is frequently high, but sometimes it may be a more stable location for atrial pacing than the atrial appendage. Steerable electrophysiologic pacing catheters may be useful in such patients.

(4) For patients who need extended temporary pacing (those with pacemaker infections or Lyme disease), a permanent pacing wire can be placed in the appropriate chamber percutaneously and sutured to the skin. This can be connected to a temporary pulse generator. In addition, it can be attached to a resterilized permanent device that can be secured to the skin as well. This leads to a very stable intermediate-term pacing system.

4. **Testing.** Once a catheter is in a stable position, threshold testing should be performed. The distal electrode on the pacing catheter is used as the cathode and connects with the negative terminal, and the ring is used as the anode and connects with the positive terminal of the generator. The pacing catheter is attached via a cable to the pacemaker generator.
   a. **Pacing capture threshold.** Pacing is started at a rate 10 to 20 beats faster than the intrinsic rate with 5 mA output. If capture is not seen at this point, the catheter needs to be repositioned. Once capture is seen, the output is slowly decreased until loss of capture is seen. The lowest capturing current is the pacing *stimulation threshold*. If the catheter is in good position, the threshold should be < 1 mA. Pacing output should be three times the threshold, but pacing is usually performed at a minimum of 5 mA (even if three times the threshold is < 5 mA). This is because minor dislodgment can cause major changes in threshold and adds a safety margin.
   b. **Sensing threshold.** This is the degree to which the pacemaker sees native cardiac signals (in millivolts). Set the pacing rate to at least 10 bpm below the patient's intrinsic rate. The sensing setting is then gradually decreased until asynchronous pacing is seen. The pacer is set at one-half the sensing threshold.
   c. **AV interval.** For dual-chamber pacing, the AV interval will need to be programmed. A default of 150 milliseconds is frequently used, but the optimal AV delay may be different in individual patients. Patients with diastolic ventricular dysfunction may need longer AV delay for ventricular filling. In patients with marginal cardiac reserve, obtaining cardiac output measurements at various AV intervals and heart rates may help determine the optimal AV interval and heart rate.
5. **Post-placement chest radiography.** A postprocedure chest radiograph must be evaluated for pneumothorax. For right ventricular apex pacing, in the posteroanterior view, the electrode tip should be located to the left of the spine. In the lateral view, the electrode tip should be directed inferiorly and anteriorly. For pacing through the coronary sinus, the tip is to the left of the spine, directed posteriorly and superiorly.
6. **Pacer care**
   a. Check the catheter insertion site daily for signs of infection and apply a new sterile dressing at regular intervals.
   b. Obtain a daily 12-lead surface electrocardiogram, ideally with and without pacing, to assess changes in native conduction and appropriate pacemaker sensing and capture.

c. Check pacemaker function daily by determining the sensing and pacing threshold, and check the underlying rhythm daily by decreasing the pacing rate gradually to "off." Abrupt termination in pacing may increase the risk of long pauses.

7. Complications

a. Related to central venous access such as hematoma at the puncture site, pneumothorax, hemothorax, air embolism, thrombosis, inadvertent arterial puncture, arteriovenous fistula, thoracic duct injury, subcutaneous emphysema, brachial plexus injury, venous thrombosis, and infection.

b. Lead dislodgment, particularly with passive fixation leads.

c. Cardiac arrhythmias such as premature ventricular contractions, premature atrial contractions, ventricular tachycardia, and RBBB. These are usually of no consequence (although the latter can result in complete heart block in the setting of a preexisting LBBB).

d. Myocardial perforation with cardiac tamponade. The unipolar recording from the tip normally shows pronounced ST elevation in comparison with the proximal electrode. ST depression from the tip is associated with perforation. If perforation is suspected, an echocardiogram should be obtained immediately to assess for pericardial effusion. Even a very small pericardial effusion can cause hemodynamic collapse. If pre/tamponade is suspected, emergency pericardiocentesis should be performed. If perforation is suspected and the patient is hemodynamically stable, the temporary pacemaker should be withdrawn only when the physician has all equipment available and is prepared to perform an emergency pericardiocentesis.

e. Pacemaker dysfunction with generator failure, oversensing or undersensing, and electrode displacement with failure to capture.

f. Complete heart block in patients with preexisting LBBB caused by catheter irritation of the right bundle.

CHAPTER 59

Sandeep Duggal

Electrical Cardioversion

I. INTRODUCTION. Delivery of electrical countershock to terminate cardiac arrhythmias is a safe and effective technique that is routinely performed in most hospitals. *Cardioversion* is defined by delivery of energy synchronized to the QRS complex, whereas random delivery of shock during the cardiac cycle (usually done for terminating ventricular fibrillation) is termed *defibrillation*.

II. MECHANISM. Although it has long been recognized that application of an electrical shock to the myocardium can restore a normal rhythm, knowledge of the fundamental mechanism underlying defibrillation remains incomplete. A rapidly delivered electric shock depolarizes the myocardial cells and creates a zone of myocardium with an extended refractory period. Activation fronts encountering tissue with a prolonged refractory period will not be able to propagate, thus terminating both macro- and micro-reentrant circuits. Atrial fibrillation and ventricular fibrillation are generally agreed to be more electrically stable rhythms and thus require higher current delivery for termination. This is likely because only regional depolarization in the path of an advancing wave front is required. The most common waveform shapes used in external defibrillation are the monophasic and biphasic waveforms. In biphasic waveforms, the polarity at each electrode reverses partway through the defibrillation waveform. The use of a biphasic waveform in cardioversion and defibrillation has been shown to be associated with an increased efficacy and may reduce the development of postshock arrhythmias.

III. INDICATIONS AND CONTRAINDICATIONS. The indications and contraindications of cardioversion are listed in Tables 59.1 and 59.2. **Cardioversion should not be performed in patients in whom the rhythm is sinus or the abnormal rhythm is secondary to increased automaticity (e.g., multifocal atrial tachycardia and junctional tachycardia). If the presenting rhythm is ventricular fibrillation or ventricular tachycardia with hemodynamic compromise, the only clear contraindication to defibrillation is clear expression of the patient's (or patient's surrogate's) informed wish not to be resuscitated.**

IV. PROCEDURE

A. Patient preparation

1. **Informed consent** should be obtained from the patient or surrogate (if the patient is unable to comprehend and give meaningful informed consent).
2. In elective cases, patient should **fast for a minimum of 6 to 8 hours**.
3. A review of the patient's medical **history and a focused physical examination** should be performed. **Special attention should be paid to the airway**. Inability to visualize the uvula, inability to open the mouth with at least 2 cm between the teeth, or difficulty in extending the neck are factors that may make potential

TABLE 59.1 Indications and Contraindications of Cardioversion

INDICATIONS

Cardioversion

1. Atrial fibrillation/atrial flutter
   - **a.** Patient with atrial fibrillation/atrial flutter > 48 h (or unknown) duration and anticoagulation for > 3–4 wk (INR 2–3)
   - **b.** Acute-onset atrial fibrillation/flutter with associated hemodynamic compromise
     1. Angina pectoris
     2. Myocardial infarction
     3. Pulmonary edema
     4. Hypotension
     5. Heart failure
   - **c.** Atrial fibrillation/flutter of unknown duration and absence of thrombus in left atrium or left atrial appendage on biplane transesophageal echocardiogram
   - **d.** Atrial fibrillation/flutter < 48 h duration → anticoagulation optional—depending on risk
2. Atrial tachycardia
3. Atrioventricular nodal reentrant tachycardia
4. Reentry tachycardias associated with Wolf-Parkinson-White syndrome
5. Ventricular tachycardia

Defibrillation

1. Ventricular fibrillation
2. Ventricular tachycardia with hemodynamic instability

CONTRAINDICATIONS

Cardioversion

1. Known atrial thrombus and no emergent indication
2. Sinus rhythm/tachycardia
3. Tachycardias associated with increased automaticity
   - **a.** Multifocal atrial tachycardia
   - **b.** Junctional tachycardia
4. Digitalis toxicity
5. Severe electrolyte imbalance and nonemergent indication
6. Unknown duration of atrial fibrillation or atrial flutter in a nonanticoagulated patient in the absence of transesophageal echocardiogram
7. Patient who cannot be safely sedated

Defibrillation

1. Prior expression of patients who wish not to be resuscitated

INR, international normalized ratio.

intubation difficult and may suggest the need for the presence of an anesthesiologist during the procedure.

4. The patient's **medication and anticoagulation status** (for patients in atrial fibrillation or flutter) should be confirmed. Because patients may not always have symptoms with arrhythmias such as atrial fibrillation and atrial flutter, convincing historical or electrocardiographic evidence of the tachycardia initiating within 48 hours of cardioversion should be documented before cardioverting a patient with atrial fibrillation or atrial flutter without adequate anticoagulation due to the risk of thromboembolism.

TABLE 59.2 Indications for Cardioversion in Patients with Atrial Fibrillation

Class I

1. Immediate electrical cardioversion in patients with paroxysmal AF and a rapid ventricular response who have electrocardiographic evidence of acute MI or symptomatic hypotension, angina, or HF that does not respond promptly to pharmacologic measures.
2. Cardioversion in patients without hemodynamic instability when symptoms of AF are unacceptable.

Class IIa

1. Electrical cardioversion to accelerate restoration of sinus rhythm in patients with a first-detected episode of AF.
2. Electrical cardioversion in patients with persistent AF when early recurrence is unlikely.
3. Repeated cardioversion followed by prophylactic drug therapy in patients who relapse to AF without antiarrhythmic medication after successful cardioversion.

Class III

1. Electrical cardioversion in patients who display spontaneous alteration between AF and sinus rhythm over short periods of time.
2. Additional cardioversion in patients with short periods of sinus rhythm who relapse to AF despite multiple cardioversion procedures and prophylactic antiarrhythmic drug treatment.

AF, atrial fibrillation; HF, heart failure; MI, myocardial infarction.

Adapted from ACC/AHA/ESC 2001 guidelines.

5. **Anticoagulation** is a key factor for patients in atrial fibrillation or flutter (Table 59.3) to prevent thromboembolism. The two key oral anticoagulants that may be used for anticoagulation are Coumadin and the newly approved dabigatran, which is used for nonvalvular atrial fibrillation or flutter. Therapeutic levels of anticoagulation for Coumadin and dabigatran differ in timing. For Coumadin, there is frequent laboratory monitoring that needs to be done with adjustment of dosing to reach a target international normalized ratio of 2 to 3, which on average takes 3 to 5 days. However, in regard to dabigatran, there is no laboratory monitoring needed, with therapeutic levels being achieved in about 12 hours. The dosing is fixed at 150 mg bid for patients with creatinine clearance (CrCl) > 30 mL/min and 75 mg bid with CrCl of 15 to 30 mL/min.
6. A 12-lead electrocardiogram (ECG) should be obtained to **confirm the presenting rhythm**, as well as to discern any suggestion of electrolyte abnormality (hypo- or hyperkalemia) or drug toxicity (digitalis). If any of these is suspected, appropriate blood levels should be checked. Routine measurement of digoxin levels is not recommended.
7. **Peripheral venous access** should be obtained for elective cases.
8. A good-quality **continuous ECG** should be obtained. Good contact of the skin and electrodes is essential, and proper skin preparation, including shaving of the chest hair (if present), is recommended.
9. **Oxygen and airway management** equipment (including suction with suction catheters, bag valve mask, laryngoscope, endotracheal tubes, and pulse oximeter) is required and should be checked prior to the procedure.

B. Technique

1. Once the patient is adequately prepared and an appropriately trained physician is present, **cardioversion patches are placed and the patient is sedated**.

TABLE 59.3 Anticoagulation Status and Cardioversion for Atrial Fibrillation/Flutter

Anticoagulation before cardioversion

1. Administer oral anticoagulation with Coumadin and ensure therapeutic INR (> 2) or dabigatran (no need for laboratory monitoring) for nonvalvular atrial fibrillation/flutter for a minimum of 3–4 wk prior to cardioversion (target INR 2–3)

or

2. Anticoagulate with heparin[a] to achieve a PTT 1.5–2 times control and screen for thrombus in left atrium or left atrial appendage by transesophageal echocardiography
   a. If no thrombus, cardiovert and continue heparin while loading Coumadin or dabigatran. In regard to Coumadin, continue the heparin until INR is therapeutic (≥ 2). If dabigatran is used, it would be reasonable to continue heparin until anticoagulation status is therapeutic, which is about 12 h

or

   b. If thrombus is visualized, anticoagulate for 3–4 wk with either Coumadin (target INR 2–3) or dabigatran and recheck transesophageal echocardiogram to confirm thrombus is resolved prior to cardioversion

3. If emergent indication

Administer heparin (unless contraindicated) to achieve PTT 1.5–2 times control prior to or immediately after cardioversion

Anticoagulation after cardioversion

Oral anticoagulation for at least 4 wk with Coumadin for a target INR 2–3 or dabigatran if no contraindications

[a]Limited data support the use of low-molecular-weight heparin (LMWH) before or after cardioversion (level of evidence: C). Use of LMWH in such clinical situations must be individualized after careful determination of the risks and benefits involved.

INR, international normalized ratio; PTT, partial thromboplastin time.

2. Electrode placement. Electrode placement on the chest is important to maximize current flow through the heart, which is what actually terminates the arrhythmia. Patches or paddles may be placed in the anteroapical or the anteroposterior position.

   a. Although the anteroapical position is easy to use in an emergency, it is associated with a lower delivery of current to the myocardium.

   b. The left anteroposterior position is commonly used for cardioversion of atrial arrhythmias because it is associated with a smaller interelectrode distance and a lesser interposition of lung parenchyma. This enhances delivery of current to the atria and improves the success of cardioversion.

   c. The right parasternal–left paravertebral electrode patch position is associated with better current delivery to both atria and is particularly useful in patients with atrial abnormalities (e.g., atrial septal defect and rheumatic valve disease). This electrode position is favored in our laboratory for cardioversion of atrial fibrillation (Fig. 59.1).

   d. Although internal cardioversion (using a right atrial catheter and a coronary sinus catheter as electrodes or using a right atrial and a posteriorly placed external electrode) has been used in the past for cardioverting morbidly obese patients or patients who are resistant to external cardioversion,

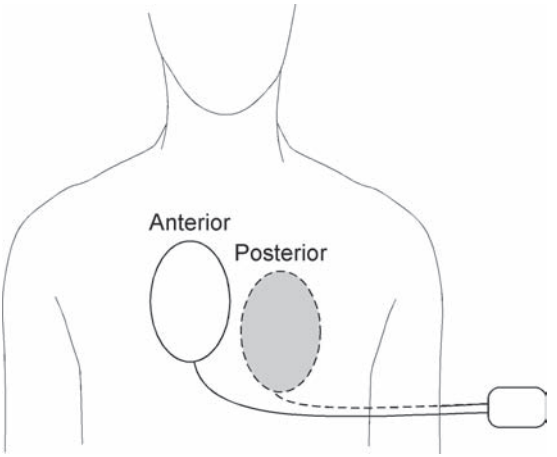

FIGURE 59.1 Right parasternal–left paravertebral electrode patch position.

it is now rarely necessary, given the widespread availability of biphasic cardioversion.

3. **Sedation.** Short-acting sedatives should be administered before all elective cardioversions, since the procedure is uncomfortable. Commonly used agents include methohexital (0.5 to 0.6 mg/kg body weight), etomidate (0.2 to 0.6 mg/kg body weight over 30 to 60 seconds), propofol (0.7 to 1.2 mg/kg, followed by 0.5 mg/kg every 3 to 5 minutes as needed), and midazolam (0.5 to 2 mg over 2 minutes, repeated every 2 to 3 minutes if necessary). Adequate sedation is confirmed by lack of response to verbal and pressure stimuli and loss of eyelash reflex. Airway, breathing, and oxygenation should be monitored until the patient makes a complete recovery, and appropriate support is provided as needed.
4. **Energy selection.** Success of cardioversion is dependent on adequate energy delivery to the heart. This in turn is dependent on the energy output, current vector, and the transthoracic impedance.
   a. The commonly used energy selection for various arrhythmias is outlined in Table 59.4. The energy selected differs between monophasic and biphasic devices.
   b. Impedance is defined as opposition to electrical flow or current. Higher impedance results in a reduction in current delivery to the myocardium. Therefore, initial energy selection should be individually tailored after consideration of important patient factors such as body habitus and the presence of lung disease, which may affect impedance. In addition, all efforts must be made to reduce impedance. A key factor that modulates impedance is electrode size, with optimal size approximating the size of the heart. Although smaller electrodes increase impedance, larger ones are associated with current wastage. The optimal diameter of an electrode for an adult patient is approximately 12 cm. Other measures to reduce impedance include application of pressure on the electrodes (approximately 12 kg) during shock delivery, shock during end-expiration, better skin–electrode interface and use of conducting gels, and repeat administration of shocks.

TABLE 59.4 Initial Energy Selection for Commonly Encountered Arrhythmias

Arrhythmia	Energy output (J)	
	Monophasic	Biphasic
Ventricular fibrillation (or unstable ventricular tachycardia)	200	120
Atrial fibrillation	200	100
Atrial flutter	50	50
Supraventricular tachycardia	150	100
Ventricular tachycardia (stable)	100	50–100

Conversely, increasing interelectrode distance and interposition of soft tissue or pulmonary parenchyma increases impedance.

5. **Synchronization.** Once the underlying rhythm is confirmed and a good-quality ECG is obtained, the synchronize mode is switched on (except for defibrillation where mode must be asynchronous). Synchronization is essential to prevent delivery of shock during the vulnerable period (from 80 milliseconds before to 30 milliseconds after the apex of T wave), with resultant ventricular fibrillation. Defibrillators are designed to time the shock to the R wave during synchronization mode. The position of the timing artifact on the R wave is confirmed on the monitor and on a printout, because the defibrillator may rarely synchronize to the T wave. Conversely, when defibrillating, the mode must be asynchronous because lack of identifiable QRS complex prevents a defibrillator in the synchronous mode from discharging.
6. **Delivery of shock.** Once the patient is adequately prepared, the electrodes are adequately positioned, and the appropriate output and mode are selected, the adequacy of sedation should be reconfirmed. The defibrillator capacitors are charged, the ancillary staff are warned to stay clear of the patient, proper synchronization is reconfirmed, and the appropriate shock is delivered. The patient is immediately assessed for adequacy of airway, breathing, and circulation. The ECG is inspected to confirm rhythm, and if sedation is still adequate, the procedure is repeated if necessary. The patient is monitored until complete recovery (generally 1 hour). Anticoagulation and antiarrhythmic medications (if any) must be addressed before discharge.

V. COMPLICATIONS OF CARDIOVERSION.

Complications after cardioversion are uncommon but include the following.

A. Thromboembolism. About 1% to 7% of patients in atrial fibrillation not anticoagulated before cardioversion develop arterial embolization after the procedure. In appropriately anticoagulated patients, the incidence of embolism is extremely low. In the Assessment of Cardioversion Using Transesophageal Echocardiography (ACUTE) trial, comparing anticoagulation for 3 weeks before cardioversion to transesophageal echocardiography (TEE)-guided therapy, the incidence of embolism was 0.5% in the conventional arm and 0.8% in the TEE-guided arm. TEE-guided cardioversion is now widely used in patients who require cardioversion urgently but who have not been adequately anticoagulated for 3 weeks.

B. Arrhythmias. It is not uncommon for patients to have premature atrial contractions or premature ventricular contractions after cardioversion. Although

some patients exhibit transient sinus arrest or atrioventricular block, this is usually self-limited. However, the ability to provide emergent temporary transthoracic pacing should be available for the rare patient who needs it. Malignant ventricular tachyarrhythmias are rare but may occur if the shock is delivered during the vulnerable period. The risk of malignant tachyarrhythmias is increased in the setting of hypokalemia or digoxin toxicity.

C. **Injuries.** The incidence and severity of chest wall burns can be reduced by the use of conductive gel, good skin and electrode contact, and use of lowest effective energy output.

D. **Airway compromise.** Excessive sedation may be associated with respiratory depression. This is more likely in the elderly or in those with hepatic or renal dysfunction. Appropriate adjustment of dose and monitoring of airway and oxygenation until complete recovery will minimize any undue effects of excessive sedation.

E. **Myocardial depression.** Cardioversion is a safe procedure with a wide margin of safety. Transient ST-segment elevation without apparent myocardial damage and minor elevations in creatine kinase myocardial band isoenzyme or in troponin I have been reported in rare instances. Rarely, patients have developed pulmonary edema after direct current cardioversion.

F. **Injuries to the operator.** Injuries to the operator are rare, with an incidence <1 in 1,700 in one series. Most are minor electrical injuries and manifest as extremity paresthesias. Major electrocution is extremely rare, and the reported cases have all been associated with equipment malfunction. Cardioversion in the presence of wet skin or nitroglycerin ointment can lead to arcing and may present a fire hazard.

VI. TROUBLESHOOTING

A. **Monitor does not work.** This is usually related to a mechanical problem. The power source, lead connections, and monitor lead electrode patches should be checked.

B. **Timing artifact falls on T wave.** Monitoring lead should be changed and the correct position of the timing artifact confirmed prior to cardioversion.

C. **Capacitor does not discharge.** When operating in the synchronized mode, the capacitor will not discharge until it recognizes a synchronized QRS. The switch should be pressed until the capacitor discharges. If this method fails, the monitoring lead should be changed and cardioversion attempted again.

D. **Cardioversion unsuccessful**

1. The first step should be to repeat the ECG to check the underlying rhythm to confirm diagnosis and to differentiate between failure to cardiovert and successful cardioversion that is followed by recurrence of the presenting arrhythmia.
2. For patients who truly fail to cardiovert, a higher energy level may be considered for a repeat attempt. A biphasic device should be used if available and all possible measures to reduce impedance applied (Section **IV.B.4.b**).
3. Another option for patients who truly fail to cardiovert is to reposition the patches to better capture the myocardium between the patches and, if not done initially, application of pressure on the electrodes (approximately 12 kg) during shock delivery to improve contact and decrease impedance.
4. Unsuccessful cardioversion may be secondary to a deranged metabolic milieu, and reversible causes (such as electrolyte imbalance or thyrotoxicosis) should be corrected.
5. Patients who are on long-term amiodarone therapy may present with atrial fibrillation as the first manifestation of amiodarone-induced hyperthyroidism, which may in turn make cardioversion more difficult.
6. In resistant cases where a biphasic device is unavailable, reversing the polarity of the electrodes with cardioversion at maximal energy, using two defibrillators to increase current, or internal cardioversion may be an option.

7. Use of appropriate antiarrhythmic drugs may facilitate cardioversion and maintenance of sinus rhythm, and the procedure may be repeated after loading with appropriate drugs. Pretreatment with 1 mg ibutilide has been shown to increase the likelihood of successful cardioversion. Ibutilide administration has been associated with the development of torsade de pointes. At our institution, patients pretreated with ibutilide are also given 1 g of IV magnesium sulfate in order to minimize this risk.
8. Predictors of unsuccessful cardioversion in chronic atrial fibrillation include long duration of atrial fibrillation, underlying structural heart disease, left atrial enlargement, and cardiomegaly.

VII. SPECIAL SITUATIONS

A. Preexisting permanent pacemaker or implantable cardioverter–defibrillator. Electric current can conduct along the implanted electrode lead and cause myocardial injury. This may manifest as a temporary or permanent increase in stimulation threshold, and, when pronounced, this may manifest as failure of capture-exit block. This can be avoided by **positioning electrodes away from the device**; therefore, the anteroposterior position is preferred. The device should be interrogated before and after cardioversion.

B. Pregnancy. Successful cardioversion has been carried out in all trimesters of pregnancy without ill effects to the mother or the fetus.

VIII. FUTURE DIRECTIONS.

A very important area for future improvement in a technique that has changed so little over the last several decades is to reduce the defibrillation thresholds. This could possibly serve to eventually eliminate pain, anesthesia, and sedation during shocks. Current research points to more effective cardioversion/defibrillation waveforms; shocks from ≥ 2 sites simultaneously and combination of shocks with cardiac pacing may prove particularly useful. In regard to the combination of shocks and cardiac pacing, we already know that pacing can influence and terminate reentrant or triggered arrhythmias. As noted in previous work with animal models and humans on the mechanisms of ventricular fibrillation and atrial fibrillation suggesting the presence of one or more drivers that may make this strategy plausible, the goal of this combination would be for less energy to be used to restore normal sinus rhythm.

IX. AUTOMATIC EXTERNAL DEFIBRILLATORS.

The automatic external defibrillator is a battery-operated microprocessor-based defibrillator that identifies tachyarrhythmias and, upon activation, delivers a shock to terminate them. This device is designed for use on an unresponsive patient with cardiac arrest. The system includes external self-adhesive pads that are applied on the victim, after which the device is switched on and cardiopulmonary resuscitation temporarily discontinued. The device analyzes the rhythm and advises the operator to press a switch to deliver a nonsynchronized shock, reanalyzes the resulting rhythm, and advises further delivery of shock if indicated. These devices are easy to use and designed to be used in the field by lay people. In various studies, the sensitivity and specificity of detection and success of termination of ventricular fibrillation and ventricular tachycardia have been > 90%, with a significant reduction in the response time for the first shock.

CHAPTER 60

Jun-Yang Lou
Venu Menon

Right Heart Catheterization

I. INTRODUCTION. In 1947, Dexter et al. (1) observed that the pressure recorded by a catheter wedged in the pulmonary artery (PA) was similar to the filling pressure in the left ventricle. In 1970, Swan and colleagues (2) reported that PA catheterization could be performed at the bedside by using a specially designed balloon-tipped catheter. This landmark observation brought right heart catheterization (RHC) to the bedside and it remains an integral part of the diagnostic armamentarium of the cardiologist. Although the routine use of RHC data to guide treatment in critically ill patients in the intensive care unit has been associated with harm, it remains the gold standard in hemodynamic monitoring, and its use can be crucial in diagnosing and treating critically ill patients with cardiovascular disease.

The utility of hemodynamic variables obtained from RHC as a diagnostic and prognostic marker in patients with acute myocardial infarction (MI), cardiogenic shock, and heart failure (HF) is well established. Proving that a clinical benefit exists for continuous RHC hemodynamic monitoring has, however, been challenging. Retrospective observational analyses on the utility have been limited by patient selection as well as survival biases. In the National Heart Lung Blood Institute–supported ESCAPE (Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness) trial, the utilization of PA catheters was not associated with worse outcomes. In this trial of 433 patients randomized to therapy for class IV HF guided by either clinical assessment or clinical assessment plus PA catheterization, there was no difference in the primary end point of days alive out of the hospital during the first 6 months after hospitalization. There was an increase in in-hospital adverse events in the PA catheter group; however, there were no deaths related to PA catheter use and no difference in in-hospital or 30-day mortality between the two groups.

II. INDICATIONS AND COMMON USES. See Table 60.1 for ACC recommendations for using PA catheterization.

(A) Acute MI complicated by hypotension, congestive heart failure, sinus tachycardia, right ventricular (RV) infarction, or mechanical complications (such as ventricular septal defect [VSD], pericardial tamponade, or acute mitral regurgitation [MR]).

(B) Assessment of volume status in patients in whom physical signs may be unreliable (e.g., morbidly obese or ventilated patients).

(C) Severe left ventricular (LV) failure to guide inotropic, diuretic, and afterload reduction management.

(D) Differentiation between various shock states (e.g., cardiogenic, distributive, or hypovolemic) and guidance of therapies.

(E) Risk stratification for patients during heart transplant evaluation.

(F) Cardiac tamponade. Although echocardiography is the diagnostic test of choice, PA catheterization may be used when echocardiography is not readily available or nondiagnostic and the risk or difficulty of pericardiocentesis is high.

(G) Assessment of the level and magnitude of an intracardiac shunt, especially if transthoracic echocardiography is nondiagnostic.

TABLE 60.1 Common Indications for the Use of Right Heart Catheterization

HF

1. To differentiate between cardiogenic and noncardiogenic pulmonary edema.
2. To differentiate between cardiogenic and noncardiogenic shock and to guide its pharmacologic or mechanical support.
3. To guide therapy in patients with biventricular HF.
4. To diagnose pericardial tamponade when echocardiography is unavailable or nondiagnostic.
5. Perioperative management of patients with decompensated HF undergoing high-risk surgery.
6. To identify reversible pulmonary hypertension in patients undergoing heart transplant evaluation.

Acute MI

1. To differentiate between cardiogenic and hypovolemic shock.
2. To guide pharmacologic and/or mechanical support of cardiogenic shock in patients with or without coronary reperfusion therapy.
3. Short-term guidance of pharmacologic and/or mechanical support in acute MR before surgery.
4. To establish severity and for short-term guidance of pharmacologic and/or mechanical support of ventricular septal rupture before surgery.
5. To guide management of right ventricular infarction that does not respond to intravascular volume expansion, low doses of inotropic drugs, and/or restoration of heart rate and atrioventricular synchrony.
6. To manage acute pulmonary edema that does not respond to treatment with diuretics, nitroglycerin, other vasodilators, and/or low doses of inotropic drugs.

Perioperative use in cardiac surgery

1. To determine the etiology of low cardiac output (hypovolemia vs. ventricular dysfunction) when exam and echocardiography are inconclusive.
2. To differentiate between right and left ventricular dysfunction and pericardial tamponade when exam and echocardiography are inconclusive.
3. To guide management of severe low cardiac output syndrome.
4. To diagnose and guide management of pulmonary hypertension in patients with systemic hypotension and evidence of inadequate organ perfusion.

PAH

1. To exclude postcapillary (elevated pulmonary capillary wedge pressure) causes of pulmonary hypertension.
2. To diagnose and establish the severity of precapillary (normal pulmonary capillary wedge pressure) pulmonary hypertension.
3. To select and establish the safety and efficacy of long-term vasodilator therapy based on acute hemodynamic response.
4. For hemodynamic assessment before lung transplantation.

HF, heart failure; MI, myocardial infarction; MR, mitral regurgitation; PAH, pulmonary arterial hypertension.

Adapted from Mueller HS, Chatterjee K, Davis KB, et al. ACC expert consensus document: present use of bedside right heart catheterization in patients with cardiac disease. *JACC*. 1998;32:840–864.

(H) **Differentiation between constrictive and restrictive cardiac physiology**.
(I) **Severe pulmonary hypertension (PH)**.
(J) **High-risk cardiac patients during preoperative, intraoperative, and postoperative periods** to monitor volume status and cardiac output (CO).
(K) **Severe adult respiratory distress syndrome (Noncardiogenic Pulmonary Edema)** during positive end-expiratory pressure trials to assess CO.

III. CONTRAINDICATIONS.

The absolute contraindications to PA catheter placement are right-sided endocarditis, a mechanical tricuspid or pulmonic valve prosthesis, thrombus or tumor in a right heart chamber, uncooperative patient, and terminal illness for which aggressive management is considered futile. Relative contraindications are profound coagulopathy (international normalized ratio > 2 or platelet count < 20,000 to 50,000), bioprosthetic tricuspid or pulmonic valve prosthesis, newly implanted pacemaker or defibrillator (unless fluoroscopic guidance is used), and left bundle branch block (LBBB). The latter is a relative contraindication because local trauma to the functioning right bundle while introducing the PA catheter may result in complete heart block and hemodynamic instability. **Consequently, temporary pacing should be immediately available when inserting a PA catheter in patients with preexisting LBBB**. Finally, it would be advisable to treat any pneumothorax/hemothorax on the contralateral lung before proceeding, in the event of an ipsilateral pulmonary injury caused by the procedure.

IV. TECHNIQUE

A. Venous introducer/sheath insertion. It is important to obtain informed consent in plain language from the patient before the procedure, addressing the utility and major complications of PA catheterization (Table 60.2). Once the procedure is ready to commence, a checklist system should be utilized to ensure safety and success, including a time-out process that confirms "right patient, right procedure, and right site of access." Using a central line kit is a convenient way to streamline the procedure. The patient should be prepped and draped in a sterile fashion from head to toe during the catheter insertion, regardless of the insertion site chosen. Multiple sites can be used for introducer placement; however, **a site that can be readily compressed, such as the internal jugular (IJ) vein, is preferred. Localization and entry into the vein is best performed under ultrasound guidance as an imaging-guided approach decreases procedural complications. Cannulation of the vein utilizing anatomical landmarks should only be used when ultrasound guidance is unavailable**.

TABLE 60.2 Complications of Right Heart Catheterization

Related to the introducer	Related to the catheter passage	Related to the catheter
Arterial puncture	Arrhythmia (PVC, NSVT, VF)	Thrombosis
Bleeding from insertion site	Complete heart block or RBBB	Thrombophlebitis
Pneumothorax	Coiling	
Nerve injury/Horner's syndrome	Valve trauma PA/RV perforation	PA infection Bacteremia ± endocarditis
Air embolism		Balloon rupture ± embolization

NSVT, nonsustained ventricular tachycardia; PA, pulmonary artery; PVC, premature ventricular contraction; RBBB, right bundle branch block; RV, right ventricular; VF, ventricular fibrillation.

1. The **IJ vein** (see Fig. 60.1) has multiple advantages, such as compressibility and minimal risk of pneumothorax. The disadvantages are the potential for accidental carotid artery puncture and limited neck mobility for patients. The IJ vein can be entered via an anterior or posterior approach. The right side is generally preferred because the vein runs a direct path to the right atrium. Often, it is easier to access the IJ vein if the patient is in the Trendelenberg position. The anterior approach uses the triangle created by the two heads of the sternocleidomastoid muscle and the clavicle. A finger should always be placed on the carotid artery to identify its position and to retract it medially. The needle should be inserted at the apex of this triangle and advanced in the direction of the ipsilateral nipple at a 45° angle. The vein can usually be entered 3 to 5 cm from the skin surface. In order to minimize complications, the vein should be found with a finder needle (20G) before using the large-bore catheter (16G) needle. Once the IJ vein is cannulated, the catheter-over-guidewire approach should be used to place the introducer. The guidewire minimizes damage to the vessel and should pass smoothly. Never force the guidewire. If difficulty in threading the wire is encountered, reattach the syringe and attempt to aspirate venous blood to ensure that the needle tip is still located in the vessel. An instructional video available from the *New England Journal of Medicine* web site (see reference) is a helpful tool for clinicians and students alike.

   An alternative IJ vein access is the posterior approach. The advantage of this approach is that it minimizes the risk of carotid artery puncture. First, the external jugular vein is located, and the IJ vein is cannulated 1 cm superior to the point where the external jugular vein crosses the lateral edge of the sternocleidomastoid muscle. Another posterior approach is to puncture along the posterior edge of the sternocleidomastoid muscle, two fingerwidths above the clavicle. The needle should be pointing toward the posterior aspect of the upper portion of the manubrium sterni.
2. **Cannulation of the subclavian vein** (see Fig. 60.1) is associated with greater patient comfort. However, there is an increased risk of pneumothorax and inadvertent subclavian artery cannulation, especially in patients on mechanical ventilation or with chronic obstructive pulmonary disease. The vein lies just under the clavicle at the insertion site for the clavicular head of the sternocleidomastoid muscle. This is where the vein should be cannulated. The subclavian artery lies just beneath the anterior scalene muscle, which is just below the subclavian vein, with the lung just underneath the artery. For better landmark definition and separation of the vein from the pleura, a rolled-up towel can be placed between the scapulae. There are two approaches to cannulating the subclavian vein: infraclavicular and supraclavicular. The infraclavicular approach is used more frequently.

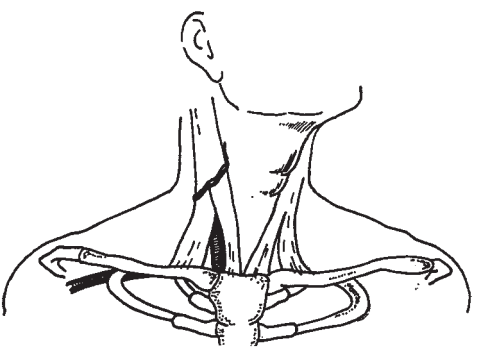

FIGURE 60.1 Neck anatomy.

The needle is inserted under the clavicle at about 1 cm lateral to the sternocleidomastoid muscle insertion point. The needle is then advanced horizontally, nearly parallel to the clavicle, toward the suprasternal notch.

With the supraclavicular approach, the vein is entered from above. The sternocleidomastoid muscle and the clavicle form an angle, and the needle is inserted at this point at a 45° angle. The vein should be cannulated no deeper than 2 cm below the skin surface. If there is uncertainty whether artery or vein has been cannulated, transduce pressure through the needle or obtain a blood gas sample to differentiate vein from artery before dilatation. An instructional video is available from the *New England Journal of Medicine* web site (see reference).

3. The **femoral vein** may also be used for PA catheterization, with the advantages being ease of cannulation, easy compressibility, and absence of pneumothorax risk. Palpate the femoral artery pulse at the level of the inguinal ligament. The femoral vein is usually located 2 cm medial to and 2 cm below the femoral artery. In some patients, the vein may lie closer to the artery. Sometimes, the Valsalva maneuver may make it easier to access the vein.

   Unfortunately, there is a high risk of bloodstream infection, associated with central venous access from femoral veins. It is recommended in the Center for Disease Control guidelines for the prevention of intravascular catheter-related infection that it not be used routinely for central venous access.
4. Venous cutdown is rarely necessary, in which case **right basilic and right median cubital veins are used**. However, due to venospasm and difficulty with catheter insertion and advancement, the antecubital route is reserved for those who have failed other routes.

B. PA catheter insertion

1. After the introducer/sheath is placed and secured, the PA catheter can be inserted. Always test balloon inflation, flush the ports, and make sure the catheter is properly calibrated before beginning the procedure. After the PA catheter is tested, insert it through the protective sterile covering and then through the introducer. Keep the balloon deflated at this stage. Ideally, **fluoroscopy and pressure waveforms should be used during PA catheter insertion for guidance**. The catheter should advance easily; if not, do not force the catheter, but make sure the introducer is properly positioned and flushed. Once the catheter has been inserted 15 to 20 cm or after the right atrial (RA) tracing is seen, **inflate the balloon** and advance across the tricuspid valve. The RV tracing should be visualized next, followed by the PA tracing, and finally the pulmonary capillary wedge pressure (PCWP) tracing (see Fig. 60.2). Not infrequently, the RV tracing is accompanied by a few premature ventricular ectopic beats. In general, the PA tracing should be reached within 50 to 55 cm if the catheter is inserted from the IJ vein or subclavian vein or 65 to 70 cm if via a femoral or an arm approach. If the PA tracing has not been visualized by this point, the catheter is likely coiled in the right ventricle. The balloon should be deflated and the catheter withdrawn. The process is repeated until proper placement is achieved.

   Once the PCWP tracing is obtained, deflate the balloon and reobtain the wedge pressure by inflating the balloon with 1.5 cm^3 of air. If the PCWP tracing is obtained even when the balloon is deflated or with < 1.5 cm^3 of air, the catheter has been advanced too far and needs to be pulled back. The pressure waveform should always be closely monitored when inflating balloon-tipped catheters to immediately identify this "overwedging." The likelihood of PA rupture and infarction increases when catheters are overwedged. In the nonventilated patient, the PCWP should be obtained at end-expiration. In general, wedging the catheter should be avoided in patients with severe PH.
2. It is much easier to float the catheter from the right IJ vein or either subclavian vein. From the femoral veins, it is slightly more difficult, **especially in patients with significant tricuspid regurgitation**. Often, the femoral PA catheter needs

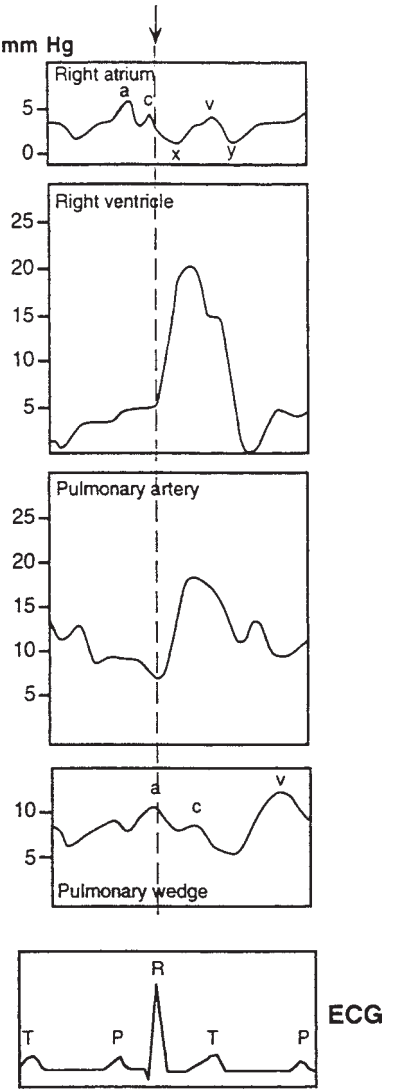

FIGURE 60.2 Waveforms.

to be inserted under fluoroscopic guidance and rotated in a continuous and clockwise motion, with the catheter tip resting just distal to the tricuspid valve until it begins to point upward. Forward motion is then applied to move the catheter into the PA. Alternatively, an S-shaped femoral Swan can be used. When using fluoroscopy, the camera should be in the anteroposterior position, and the balloon should be inflated under fluoroscopy.

3. Finally, check the catheter placement and check for pneumothorax after the procedure by obtaining a chest x-ray film. Catheter placement may be difficult in patients with low CO, severe tricuspid regurgitation, PH, or a dilated right atrium or right ventricle.
4. Catheter advancement may be facilitated by a deep inspiration or, in more difficult cases, by a guidewire with a 0.021" diameter. The wire can be placed inside the distal lumen of the catheter, improving the stiffness and making the catheter easier to manipulate. The distal end of the guidewire should always be under manual control and a hemostat can be placed on the end of the guidewire to ensure this.

V. COMPLICATIONS.

See Table 60.2.

VI. TROUBLESHOOTING.

See Table 60.3.

VII. WAVEFORMS.

See Figure 60.2.

A. Right atrium. When interpreting hemodynamic data, it is helpful to align pressure tracings with simultaneous electrocardiography (ECG). RA systole occurs after the *p* wave on the ECG and produces the *a* wave on the right atrial pressure (RAP) tracing. Atrial relaxation, the *x* descent, occurs with a decline in pressure. Tricuspid valve closure produces a slight upward deflection during the *x* descent, which is known as the *c* wave. The *c* wave follows the *a* wave by the PR interval and correlates with RV systole. The *v* wave occurs near the end of the *t* wave on ECG and marks atrial filling during early diastole. Finally, the *y* descent marks the opening of the tricuspid valve during RV diastole and emptying of the atrium. In the normal right atrium, the peak *a* wave is greater than the peak *v* wave.

B. Right ventricle. RV systole follows the QRS complex of the ECG. With ventricular relaxation, the pressure declines and the tricuspid valve opens. During the continuous filling from the right atrium, a small *a* wave is produced that marks atrial contraction and occurs after the *p* wave and just before the QRS on the ECG. End-diastole is the point just after the *a* wave and just before ventricular contraction. The peak systolic and end-diastolic measurements are used for right ventricular pressures (RVPs).

TABLE 60.3 Troubleshooting in Right Heart Catheterization

Problems	Solutions
Arrhythmia	Catheter may be in the RVOT. Pull the catheter back or advance forward
No PCWP tracing	Catheter tip is usually not advanced far enough, balloon has ruptured, or the catheter is coiled in the right ventricle. Use fluoroscopy for guidance
Continuous PCWP tracing	Balloon is inflated or the catheter is too far advanced ("overwedged")
Abnormal tracing	Catheter tip is up against a vessel wall or is too far advanced
Damped tracing	Tubing is kinked, air or thrombus is in the catheter, or catheter tip is up against the vessel wall. Flush and/or withdraw the catheter
Change in pressure tracing	Improper calibration, change in patient position or catheter location

PCWP, pulmonary capillary wedge pressure; RVOT, right ventricular outflow tract.

C. Pulmonary artery. The normal pulmonary arterial pressure (PAP) tracing contains a *v* wave, which corresponds to RV systole and follows the QRS complex. During the relaxation period, pulmonic valve closure produces the incisura, a notch during pressure decline on the *v* wave. The trough of the pressure decline marks end-diastole. Pulmonic arterial systolic pressure, end-diastolic pressure, and mean pressure are recorded.

D. The **PCWP tracing** is a transmitted left atrial pressure (LAP) and is considered an approximation for left ventricular end-diastolic pressure (LVEDP), i.e., LV preload. The waveforms are similar to an RAP tracing, with the *a* wave corresponding to left atrial systole, the *x* descent to relaxation, the *v* wave to filling, and the *y* descent to emptying. However, in contrast to the right atrium, the *v* wave is greater than the *a* wave in the left atrium and the *c* wave is not seen due to transmission through the pulmonary vasculature. Mean PCWP, *a* wave pressure, and *v* wave pressure are generally measured during end-expiration when intrathoracic pressures are equal to the atmospheric pressure.

VIII. PITFALLS OF THE PA CATHETER.

While the PA catheter remains the gold standard in monitoring hemodynamics, care should be taken to avoid errors in measurement and interpretation. Clinical decisions based on misleading PA catheter data may adversely impact on patient outcome.

Calibration and referencing. Before the PA catheter enters the body, it should be flushed to eliminate bubbles and calibrated/zeroed at the level of the patient's mid-thorax level, i.e., phlebostatic level. Serial hemodynamic measurements should be performed with the reference point moved to match the phlebostatic level, which changes with patient position.

Proper interpretation of PA catheter data is essential and must be carried out with an understanding of the clinical context. For example, the PCWP is an accurate measurement of LV filling pressure, except in pulmonary veno-occlusive disease (PCWP > LAP) or in mitral stenosis and obstructive left atrial myxoma (PCWP = LAP > LVEDP). In MR, LAP is greater than LVEDP; in acute aortic insufficiency or a noncompliant ventricle, LVEDP is greater than LAP. Furthermore, alterations in pulmonary alveolar and intrathoracic pressures (e.g., in respiratory failure with high positive end-expiratory pressure) can also significantly alter the PAWP waveform.

IX. CARDIAC OUTPUT

A. Measurement via **thermodilution** technique may be performed at the bedside but should be avoided in the setting of severe tricuspid regurgitation, intracardiac shunts, existing catheter thrombosis, and low CO.

(1) Prefill syringes with 10 mL of room temperature indicator (usually normal saline), then connect the syringe to the distal port of the PAC, which should rest in the right atrium.

(2) Check the position of the catheter. Make sure you can obtain the PCWP tracing with 1.5 cm^3 of air and no less. Then deflate the balloon and ensure the catheter tip rests in the proximal PA.

(3) After properly attaching the tubing to the thermistor, inject the contents of the syringe five separate times. Discard the highest and lowest values, taking the mean measurement of the remaining three values.

B. Calculation of CO using the **Fick equation**:

(1) Obtain patient's weight in kilograms.

(2) Draw peripheral arterial blood gas to obtain systemic oxygen saturation (Ao_2%).

(3) Draw blood gas from the distal lumen of the PA catheter (Vo_2%).

(4) Draw hemoglobin.

(5) $CO = [Wt \times 3\ mL\ O_2/kg]/[(Ao_2\% - Vo_2\%) \times 1.36 \times Hgb \times 10]$.

(6) Oxygen consumption can be measured from a metabolic hood or a Douglas bag. It can also be estimated as 3 mL O_2/kg.

TABLE 60.4 Clinical Scenarios in Right Heart Catheterization

Clinical scenarios	Data	Tracing
RV infarct	↑ RAP, ↓ CO, ↓ BP RAP > PCWP, steep *y* descent, square root sign (morphology in RV tracing diastolic "dip and plateau")	Figure 60.3
Acute mitral regurgitation	↑ PCWP, prominent *v* wave	Figure 60.4
Acute VSD	Oxygen saturation step up from the right atrium to PA	
Noncardiac pulmonary edema	Normal to low PCWP, with abnormal chest X-Ray	
Massive pulmonary embolism	↓ BP, ↓ CO, ↑ PAP, normal PCWP	
Pulmonary arterial hypertension (cor pulmonale)	↑ RAP, ↑ RVP, ↑ PAP, prominent *a* and *v* waves and normal PCWP. PAP and RV systolic pressure may reach systemic levels	
Tamponade	Diastolic equalization of pressures (RAP = RV diastolic pressure = PCWP) ↑ RAP, ↑ RVP, ↑ PCWP Paradoxical pulse, blunted *y* descent, prominent *x* descent on RA tracing	Figure 60.5
Constrictive pericarditis	↑ RAP, ↑ PCWP Dip and plateau in RVP tracing, M- or W-shaped jugular venous pressure tracing	Figure 60.6
Tricuspid regurgitation	↑ RAP, ↑ RV EDP Blunted *x* descent, prominent *v* wave, steep *y* descent, and ventricularization of RAP	

BP, blood pressure; CO, cardiac output; EDP, end-diastolic pressure; PA, pulmonary artery; PAP, pulmonary arterial pressure; PCWP, pulmonary capillary wedge pressure; RA, right atrial; RAP, right atrial pressure; RV, right ventricular; RVP, right ventricular pressure; VSD, ventricular septal defect.

X. CLINICAL SCENARIOS. See Table 60.4.

A. Shock (see Table 60.5). Four classes of shock are characterized: hypovolemic, cardiogenic, distributive, and anaphylactic. Hypovolemic shock is due to a profound decrease in venous return and ventricular preload and can be caused by hemorrhage, dehydration, increased positive intrathoracic pressure, and depressed vasomotor tone. Hemodynamic data consist of decreased blood pressure (BP), CO, and PCWP with increased systemic vascular resistance (SVR). Cardiogenic shock results from failure of the cardiac pump to maintain adequate output and can be caused by a change in loading conditions (decrease in preload due to tamponade or increase in preload due to VSD), contractility (acute ischemia or infarction), or an abrupt increase in afterload. Low BP and CO but high PCWP and SVR characterize cardiogenic shock due to LV dysfunction. Contrary to classic teaching, patients in cardiogenic shock from predominant LV failure can have normal to reduced SVR. This drop in SVR in the setting of an MI is most commonly seen after a large anterior wall MI and among the elderly and is likely mediated by profound nitric oxide release in the setting of acute myocardial injury. In general, predominant elevation of RAP is indicative of RV failure, and isolated elevation of the PCWP is indicative of LV failure. The

TABLE 60.5 Interpreting Right Heart Catheterization Data in Shock

	Blood pressure	PCWP	CO	SVR
Distributive	Low	Low	High	Low
Cardiogenic	Low	High	Low	High/normal/low
Hypovolemic	Low	Low	Low	High

CO, cardiac output; PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance.

hemodynamic indices characteristic of distributive shock are low BP, PCWP and SVR but high CO. A depressed CO as well as low BP, PCWP, and SVR can characterize the late phase of distributive shock. Finally, in terms of hemodynamics, not much is known about anaphylactic shock. However, there is a hyperkinetic phase, characterized by low SVR and high CO, as well as a later hypokinetic phase, dominated by profound hypovolemia with decreased CO.

B. RV failure (see Fig. 60.3 and Table 60.4) may be due to RV infarction, severe PH, pulmonary embolism, or increased preload due to left-to-right intracardiac shunt. An RV infarct (see Fig. 60.3) produces increased RAP and RV end-diastolic pressure, with low CO and BP. Because the right ventricle dilates and becomes less distensible, a dip-and-plateau pattern on the RVP tracing is seen. On the RAP tracing, there is a steep *y* descent. In the setting of severe tricuspid regurgitation and RV infarction, the dip-and-plateau pattern is lost. A blunted *x* descent, prominent *v* wave, and steep *y* descent are then seen on RAP tracing.

C. Acute MR (see Fig. 60.4 and Table 60.4) may be due to papillary muscle dysfunction or rupture. In this setting, the left atrium is subjected to a sudden increase in pressure. Regurgitation produces a large *v* wave in the PCWP tracing that occurs after the *T* wave on ECG. A *v*-wave pressure that is twice the value of PCWP is considered to be abnormal. In chronic MR, the *v* wave may be modest in amplitude due to chronic atrial dilatation. Other causes for prominent *v* waves are severe tricuspid regurgitation and VSD.

D. Tricuspid regurgitation (see Table 60.4). The RA systolic wave may resemble the RV tracing. There is increased RAP and RV end-diastolic pressure, a blunted *x* descent, a prominent "*c*-*v*" wave, and a steep *y* descent on RAP tracing.

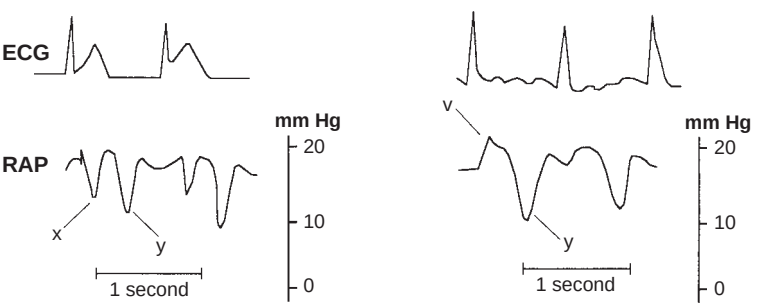

FIGURE 60.3 Right ventricular infarction without tricuspid regurgitation (*left*); right ventricular infarction with tricuspid regurgitation (*right*).

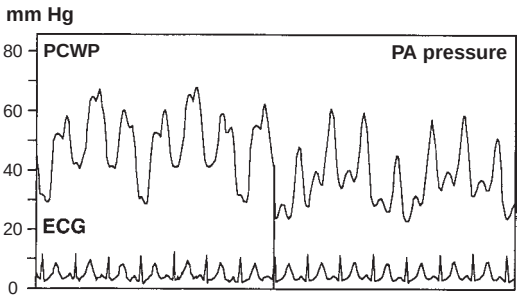

FIGURE 60.4 Acute mitral regurgitation.

E. Cardiac tamponade (see Fig. 60.5 and Table 60.4). The hallmark of tamponade is diastolic equalization of pressures, where RAP = RVP = PCWP. The RA waveform is characterized by a deep *x* descent and absent *y* descent (due to lack of RV filling at the beginning of diastole). In addition, RAP, RVP, and PCWP are increased.

F. Constrictive pericarditis (see Fig. 60.6 and Table 60.4) is characterized by brisk ventricular filling during early diastole and limited ventricular filling during late diastole. The constriction results in the elevation and equalization of RV end-diastolic pressure and LVEDP. The dip-and-plateau waveform is seen in constrictive pericarditis as well as restrictive cardiomyopathy, RV infarct, and massive pulmonary embolism.

G. Massive pulmonary embolism (see Table 60.4). There is ventricularization of the PA waveform with rapid end-systolic descent and a hardly visible, or absent, dicrotic notch due to obstruction in the PA.

H. Restrictive cardiomyopathy (see Table 60.6) includes a heterogeneous group of illnesses, such as hemochromatosis, amyloidosis, and endomyocardial fibrosis. This leads to impaired diastolic filling of the ventricles. There is a prominent *y* descent, but the dip-and-plateau waveform is less pronounced due to a pandiastolic hindrance to ventricular filling.

I. Pulmonary hypertension (see Table 60.4). PH is defined as a mean PAP > 25 mm Hg at rest. It can be caused by elevated pulmonary venous pressures due to LV dysfunction, left-sided valvular disease, and/or volume overload (i.e., elevated PCWP). It may also be caused by intrinsic pathology within the pulmonary arterial bed, i.e., pulmonary arterial hypertension (PAH). PAH is defined as mean PAP > 25 mm Hg at rest with PCWP < 15 mm Hg. Compensatory changes in the right heart to chronic PH or PAH result in elevations in RV and PA pressures with prominent *a* and *v* waves.

XI. FORMULAS (see Table 60.7)

(1) CO by Fick equation in L/min:

$$CO = [Wt \times 3\ mL\ O_2/kg]/[(Ao_2\% - Vo_2\%) \times 1.36 \times Hgb \times 10]$$

where Wt is weight in kilograms, Ao_2% is systemic arterial oxygen saturation, Vo_2% is mixed venous oxygen saturation, and Hgb is hemoglobin concentration.

(2) Cardiac index (CI) in L/min/m^2:

$$CI = CO/BSA$$

where BSA is body surface area in m^2.

(3) Stroke volume (SV) in mL/beat:

$$SV = CO/\text{heart rate}$$

(4) Pulmonary vascular resistance (PVR) in dynes × s/cm^5:

$$PVR = [(\text{mean PAP} - PCWP) \times 80]/[CO]$$

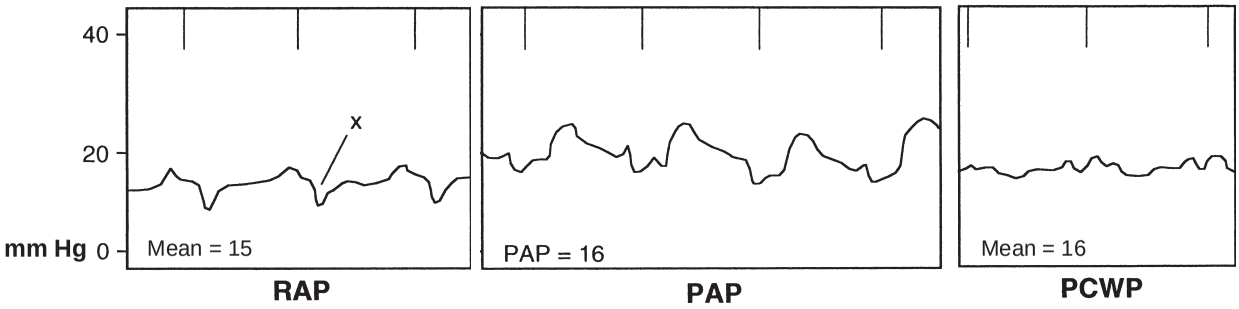

FIGURE 60.5 Cardiac tamponade.

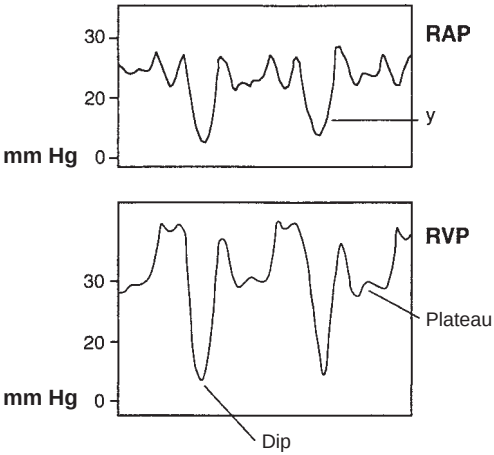

FIGURE 60.6 Constrictive pericarditis.

TABLE 60.6 Differentiating Diastolic Dysfunction

	Constrictive pericarditis	RV infarct	Tamponade	Restrictive cardiomyopathy
Pulsus paradoxus	Rare	Occasional	Frequent	Rare
RA waveforms	Prominent *y* descent	Prominent *y* descent	Prominent *x* descent	Prominent *y* descent
Equalization of diastolic pressures	Frequent	Frequent	Frequent	Rare
Dip and plateau (RV)	Frequent	Frequent	Absent	Frequent

RA, right atrial; RV, right ventricular.

where PAP is pulmonary arterial pressure and PCWP is pulmonary capillary wedge pressure.

(5) **Systemic vascular resistance** in dynes × s/cm^5:

$$SVR = [(MAP - CVP) \times 80]/[CO]$$

where MAP is mean arterial pressure and CVP is central venous pressure (can also substitute RAP for CVP).

(6) **Estimate of O_2 consumption** = 125 mL/min/m^2 = 3 mL O_2/kg.

(7) **O_2 content** = (Ao_2% – Vo_2%) × 1.36 × Hgb × 10.

(8) **CO = O_2 consumption/O_2 content**.

XII. INTRACARDIAC SHUNT. The existence of an intracardiac shunt can be evaluated by using a PA catheter and performing a saturation "run." Blood samples for oximetry are obtained from the PA as well as regions of the right ventricle, right atrium, superior vena cava, and inferior vena cava. With the catheter positioned in the PA, CO by the Fick equation can be obtained. As the operator manipulates and pulls the catheter back under fluoroscopic and pressure guidance, a blood sample from each location is

TABLE 60.7 Normal Values and Formulas

	Formula	Normal values
RA		0–8 mm Hg
RV		Systolic 15–30 mm Hg Diastolic 0–8 mm Hg
PA		Systolic 15–30 mm Hg Diastolic 3–12 mm Hg Mean 8–20 mm Hg
PCWP		6–12 mm Hg
CO	Fick equation: $[Wt \times 3\ mL/kg]/[(Ao_2\% - Vo_2\% \times 1.36 \times Hgb \times 10]$	4–8 L/min
CI	CO/BSA	2.8–4.2 L/min/m^2
SV	CO/HR	40–120 cm^3/beat
SVR	[(MAP – CVP) × 80]/CO	770–1,500 dynes s/cm^2
PVR	[(PAP – PCWP) × 80]/CO	20–120 dynes s/cm^2
Shunt fraction (Q_p/Q_s)	$[Ao_2\% - Vo_2\%]/[PVo_2\% - PAo_2\%]$	> 2.0 large defect 1.5–2.0 moderate defect

Ao_2%, peripheral arterial oxygen saturation; BSA, body surface area; CI, cardiac index; CO, cardiac output; CVP, central venous pressure; Hgb, hemoglobin; HR, heart rate; MAP, mean arterial pressure; PA, pulmonary artery; PAo_2%, pulmonary artery oxygen saturation; PAP, pulmonary arterial pressure; PCWP, pulmonary capillary wedge pressure; PVo_2%, pulmonary vein oxygen saturation often assumed to equal Ao_2 in left-to-right shunt; PVR, pulmonary vascular resistance; Q_p, pulmonary flow; Q_s, systemic flow; RA, right atrium; RV, right ventricle; SV, stroke volume; SVR, systemic vascular resistance; Vo_2%, mixed venous oxygen saturation, Wt, weight in kilograms.

aspirated. A left-to-right shunt is suggested when a "step up," or increase, in the oxygen saturation in one chamber exceeds the oxygen saturation of a proximal compartment by more than 7% in the case of an atrial shunt or more than 5% in ventricular or great vessel shunts.

In a normal setting, the effective pulmonary blood flow should equal the systemic blood flow ie. $Q_p/Q_s = 1$. However, with a left-to-right shunt, pulmonary blood flow is equal to systemic blood flow plus the amount of shunt flow. Conversely, in a right-to-left shunt, the effective pulmonary blood flow is decreased by the amount of shunt flow. The shunt fraction is the ratio of pulmonary to systemic flow, denoted Q_p/Q_s (where Q_p is pulmonary flow and Q_s is systemic flow). For an atrial septal defect, the mixed venous oxygen saturation is computed as the sum of three times the superior vena cava saturation plus the inferior vena cava oxygen saturation, and the total is divided by 4.

A. Calculation of left-to-right shunt

(1) Shunt fraction = pulmonary flow in L/min (Q_p)/systemic flow in L/min (Q_s)

(2) $Q_p = O_2$ consumption/$[10 \times (PVo_2\% - PAo_2\%)]$

where PVo_2% is pulmonary vein oxygen saturation and PAo_2% is pulmonary artery oxygen saturation.

(3) $Q_s = O_2$ consumption/$[10 \times (Ao_2\% - MVo_2\%)]$

where Ao_2% is peripheral arterial oxygen saturation and MVo_2% is mixed venous oxygen saturation.

(4) Simplified calculation using saturation only:

$$Q_p/Q_s = (Ao_2\% - MVo_2\%)/(PVo_2\% - PAo_2\%)$$

Important note: A shunt fraction of > 1.5 often necessitates shunt closure.

CHAPTER 61

Mosi K. Bennett
W.H. Wilson Tang

Endomyocardial Biopsy

I. INDICATIONS AND CONTRAINDICATIONS. Endomyocardial biopsy (EMB) is less used now as a diagnostic tool for patients with systolic or diastolic dysfunction with the availability of more accurate noninvasive imaging techniques such as magnetic resonance imaging. Currently, the major indications for EMB are monitoring for allograft rejection after cardiac transplantation, as well as ruling out some potentially treatable forms of myocarditis. The role for this procedure in other disorders, such as arrhythmogenic right ventricular dysplasia, remains controversial because the diagnostic accuracy must be considered in relation to the lack of proven effective therapy. Potential indications and contraindications for EMB are listed in Tables 61.1, 61.2, and 61.3.

II. PATIENT PREPARATION. As with any other procedure, extensive patient education and informed consent are necessary before starting the procedure. Patients undergoing EMB should be informed that there is a very small chance (<1% in experienced hands) of cardiac perforation, with potential urgent cardiovascular surgery and even death as a consequence.

Sedation is seldom needed but may help anxious patients better tolerate the procedure. Monitoring of heart rate by continuous electrocardiographic telemetry, blood pressure (noninvasively), and pulse oximetry is essential throughout the procedure. The patient should be monitored for a couple of hours after the procedure, as myocardial perforation with subsequent pericardial effusion may only become apparent some time after EMB. The patient is always positioned flat regardless of the venous approach. Venous access may be obtained through the internal jugular (most common), subclavian, or femoral veins. Ultrasound guidance or maneuvers to increase central venous pressure such as Valsalva, leg elevation with a wedge, and Trendelenburg position are helpful in obtaining venous access. Most centers use fluoroscopy as the imaging method of choice to guide EMB. However, echocardiography can also be used, particularly when radiation exposure needs to be minimized, such as in pregnant women.

III. DEVICES

A. Sheath. Venous access is obtained using the Seldinger technique, and the sheath is always placed over a guidewire so as not to damage any vascular structures. A standard short sheath (11 cm, 7F or 8F) is generally sufficient for the right internal jugular or any subclavian approach. The intermediate-length sheath (24 or 35 cm) may be helpful to reduce venous angulation or to avoid damaging the vessel wall or a suture line when inserting the bioptome in patients with prior heart transplantation. For the left internal jugular approach, a longer sheath (40 cm, 7F) is used with a single- or double-curved tip based on operator preference and venous and cardiac anatomy. For a femoral approach, a curved 7F, 85-cm-long transseptal sheath is used, as it can be easily positioned into the right ventricle.

TABLE 61.1 Common Indications for Endomyocardial Biopsy

Clinical scenarios	Class of recommendation
New-onset heart failure of <2 wk duration associated with a normal-sized or dilated left ventricle and hemodynamic compromise	I
New-onset heart failure of 2 wk to 3 mo duration associated with a dilated left ventricle and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 1–2 wk	I
Heart failure of >3 mo duration associated with a dilated left ventricle and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 1–2 wk	IIa
Heart failure associated with a DCM of any duration associated with suspected allergic reaction and/or eosinophilia	IIa
Heart failure associated with suspected anthracycline cardiomyopathy	IIa
Heart failure associated with unexplained restrictive cardiomyopathy	IIa
Suspected cardiac tumors	IIa
Unexplained cardiomyopathy in children	IIa

DCM, dilated cardiomyopathy.

Adapted from AHA/ACC/ESC 2007 Consensus Statement.

TABLE 61.2 Conditions Involving the Heart in Which Endomyocardial Biopsy Can Establish the Diagnosis, Listed According to the Presence or Absence of Proven Effective Therapy

Treatable conditions	Less treatable conditions
Cardiac allograft rejection	Myocarditis (non–giant cell)
Cardiac amyloidosis	Arrhythmogenic right ventricular dysplasia
Giant cell myocarditis	Glycogen storage disease
Hypereosinophilic syndrome	Rheumatic carditis
Staging of anthracycline toxicity	Chagas disease
Cardiac sarcoidosis	
Cardiac hemochromatosis	
Lyme carditis	
Fabry's disease	

B. Bioptome. There are two basic types of bioptomes: (1) independent and stiff, which does not require a long sheath but does rely on the operator skill to be maneuvered safely into the right ventricle, and (2) flexible, which requires a longer sheath advanced into the right ventricle for positioning. Resterilizable and reusable bioptomes are widely used, but disposable bioptomes are also available. For internal jugular and subclavian approaches, 50-cm-long bioptomes are used, whereas for femoral access, the bioptomes used are longer (up to 105 cm).

TABLE 61.3 Relative Contraindications for Endomyocardial Biopsy

Informed consent not obtained
Patient not cooperative (confused, agitated, etc.)
Profound hemodynamic compromise
No cardiac surgery backup available
Coagulopathy (INR > 1.5)
Mechanical tricuspid prosthesis
Significant right-to-left shunt (risk of air embolus)
Thinning of myocardium after MI or in case of ARVD
RA or RV thrombus

ARVD, arrhythmogenic right ventricular dysplasia; INR, international normalized ratio; MI, myocardial infarction; RA, right atrial; RV, right ventricular.

IV. TECHNIQUE. Right ventricular endomyocardial biopsies can be performed from either the right or left internal jugular, subclavian, or femoral veins. If necessary, a left ventricular EMB can be obtained via the femoral artery approach, although this is rarely necessary.

A. Right ventricular biopsy

1. **Internal jugular vein approach.** After standard preparation and local anesthesia, the required anatomic landmarks (see Chapter 58) are identified. A pilot puncture with a 22G needle can be made to localize the vein. The internal jugular vein is punctured with an 18G (Cook) needle, and the sheath is introduced using standard technique. The bioptome, with jaws closed and tip straightened, is advanced under fluoroscopic or echocardiographic guidance across the atrial suture line (in allografts) until its tip lies against the lower third of the lateral right atrial wall. It is then rotated gently counterclockwise and simultaneously advanced into the right ventricular cavity. During this procedure, the tip is gently unstraightened. Rotation is continued until the catheter reaches the apical half of the right ventricle and the handle clamp points in the posterior direction. At this point, the tip of the bioptome rests on the interventricular septum. The position is confirmed by inability to further advance the bioptome, the generation of premature ventricular contractions, and fluoroscopic appearance. Generation of premature atrial contractions or absence of ventricular ectopy may indicate that the bioptome was advanced in the right atrium or in the coronary sinus. If there is any doubt about the position, the bioptome is withdrawn and the process repeated. Once in the desired position, the bioptome is withdrawn about 0.5 to 1 cm and advanced again after the jaws have been opened. When it touches the endocardium, the jaws are closed and the bioptome is gently withdrawn with its jaws closed under continuous fluoroscopic guidance. A small tug is often felt while withdrawing, but excessive tugging and multiple premature ventricular contractions should prompt consideration of repositioning. Usually four to six biopsy specimens are obtained in different areas of the septum to reduce sampling error. Once the procedure is completed, the venous sheath is removed and hemostasis achieved. Patients are monitored for about 2 to 4 hours after EMB.
2. **Femoral vein approach.** After standard preparation and local anesthesia, the required anatomic landmarks (see Chapter 60) are identified. The right (more common) or the left femoral vein is punctured with an 18G (Cook) needle, and a 0.038" guidewire is advanced up to the right atrium. A long (85-cm) 7F sheath

with dilator is advanced over the wire, and on entering the right atrium the dilator is withdrawn. The tricuspid valve is crossed with the help of the guidewire (a balloon-tipped catheter can also be used), and the sheath is advanced into the right ventricle toward the intraventricular septum. The pressure tracing, occurrence of ventricular ectopy, and fluoroscopy are used to confirm position. The side port of the sheath may be connected to a slow continuous intravenous infusion to prevent clot formation inside the sheath, especially if a long procedure is anticipated. A long nonsteerable bioptome is advanced through the sheath and is used to acquire samples. Biopsies are taken in a manner similar to that of the internal jugular vein approach.

3. **Subclavian vein approach.** After standard preparation and local anesthesia, the required anatomic landmarks (see Chapter 60) are identified. The subclavian vein is punctured using an 18G (Cook) needle followed by insertion of the sheath. The occurrence of ventricular ectopy and fluoroscopic images are used to confirm a position pointing toward the interventricular septum. Biopsies are taken as with the internal jugular vein approach.

B. Left ventricular biopsy

1. **Femoral arterial approach.** After standard preparation and local anesthesia, the required anatomic landmarks are identified. The right (more common) or left femoral artery is punctured with an 18G (Cook) needle, and a short 8F sheath is inserted while a 0.035" long exchange guidewire is advanced up to the ascending aorta. A regular-length 7F pigtail catheter is advanced over the wire, and the aortic valve is crossed in the conventional manner. Afterward, the pigtail catheter is removed, while leaving the guidewire in the left ventricle, and exchanged with an 8F long, curved guiding sheath. The tip of this sheath is directed toward the interventricular septum, distal to the mitral apparatus, away from the thinner posterobasal wall. The position of the sheath is carefully reconfirmed (fluoroscopic images in two angulations and pressure tracings), and 5,000 U heparin is given intravenously before insertion of the bioptome. A long, nonsteerable bioptome is then advanced through the guiding sheath, and biopsy samples are collected as with right ventricular biopsy. It is important to note that catheters must be aspirated and flushed after each biopsy, since air can enter the sheath and clots can form in the sheath after removing the bioptome. Heparin is not reversed with protamine at the end of the procedure as it is thought to minimize thrombus formation at the biopsy sites.

V. COMPLICATIONS. In general, EMB can be performed more safely in heart transplant recipients than in patients with native hearts, because of the scarred and thickened pericardium in transplanted patients.

A. Mortality. Procedure-related deaths have been reported to be <0.05% in contemporary series.

B. Cardiac perforation and tamponade. The reported incidence of cardiac perforation is 0.3% to 0.5%, which can rapidly result in tamponade. The risk can be minimized by careful monitoring of catheter position to ensure that biopsies are obtained from the thicker interventricular septum and by gentle catheter advancement and EMB procurement. Symptoms of chest pain during or after the procedure, shortness of breath, a pericardial rub, or altered hemodynamics should suggest potential perforation and should prompt urgent echocardiography to rule out a new pericardial effusion or tamponade. Patients in whom a new pericardial effusion is suspected or detected should be monitored in the hospital for evidence of increasing pericardial effusion or tamponade, and an echocardiogram should be repeated at intervals as necessary and before discharge.

In patients early after heart transplantation, the atrial suture line also poses a higher risk of perforation. Very gentle advancement of the bioptome (and pulling back if any resistance is felt) and use of a longer sheath to pass the suture line if

needed will reduce this risk. Patients with suspected perforation should be closely monitored, and echocardiography, fluoroscopy, and cardiac tomography scanning can be used to confirm the diagnosis.

For both cardiac perforation and tamponade, careful monitoring is usually sufficient, although pericardiocentesis or even urgent cardiac surgery may be necessary if hemodynamic compromise develops.

C. Thromboembolism. Right-sided thromboembolism during EMB is possible in theory, but does not cause any clinically significant sequelae if it occurs. The risk of arterial embolization during left ventricular EMB is higher, owing to the longer sheath, and may have catastrophic consequences. Using heparin during a left-sided approach and aspirating air and flushing the sheath before inserting the bioptome minimize the risk of embolism.

D. Arrhythmia. Occasionally, a sustained atrial or, less commonly, a ventricular tachycardia is induced by EMB. These arrhythmias are almost always stopped by touching the wall of the right atrium or ventricle with the bioptome. Bradyarrhythmic episodes or bundle branch block induced by EMB is very rare and responds only to β_1-stimulants and not to atropine in heart transplant patients.

E. Tricuspid valve (or mitral valve for left ventricular biopsy) dysfunction. The bioptome can damage the chordae or papillary muscle and produce significant valvular regurgitation. The risk of this complication is minimized by careful confirmation of bioptome position before sampling. The cumulative risk of this complication is greater in heart transplant patients because they undergo many EMB procedures.

F. Damage to vena cava, coronary sinus, hepatic vein, and coronary arteries. Gentle advancement of the bioptome, use of a longer sheath, retraction of bioptome whenever resistance is felt, and position confirmation with multiple fluoroscopic views may minimize these complications. Fistula formation from a coronary artery branch to the right ventricle has occurred following EMB but is of no clinical significance.

G. Local complications. Hematoma, local infection, and injury to the lung (pneumothorax, incidence 0.9%) and nerve (recurrent laryngeal palsy and Horner's syndrome) are possible but rare while achieving vascular access. Careful identification of anatomic landmarks reduces the risk of these complications.

H. Pain. The EMB itself is usually painless, but some patients experience some mild degree of pain when the bioptome touches the heart or when a biopsy is taken.

ACKNOWLEDGMENTS: *The authors would like to thank Drs. Milind Shah, Wilfried Mullens, and Zuheir Adams for their contributions to earlier editions of this chapter.*

Management of Continuous-Flow Ventricular Assist Systems: Troubleshooting and Complications

I. INTRODUCTION. This chapter is designed to briefly overview the mechanics of continuous-flow left ventricular assist systems (LVASs) and highlight the diagnosis and management of immediate and long-term complications of LVASs. LVAS support has emerged as the standard of care in patients with refractory stage D heart failure (HF) as both bridge to transplant and destination therapy.

(A) Continuous-flow LVASs are the most recent advances in permanent mechanical support systems.

(B) Continuous-flow LVAS can use either centrifugal-flow or axial-flow blood pumps. Both are designed similarly with a single rotating impeller that is designed to increase pressure and flow within the system.

(C) Bearings constrain the impeller within the device, allowing rotational movement. The bearings may be of three types: magnetic levitation, hydrodynamic, and blood immersed.

(D) Continuous-flow LVASs are smaller than pulsatile ventricular assist devices (VADs) that can accommodate most patients, including small women and children.

(E) Blood flow capacity is up to 10 L/min, which can provide constant unloading of the left ventricle. Unlike pulsatile-flow pumps that are primarily preload dependent, continuous-flow VADs are both afterload and preload dependent.

(F) As pulsatile VADs had either an automatic or fixed rate and stroke volume, continuous-flow VADs can be modulated by changes in the rotational velocity of the impeller.

(G) Axial-flow pumps include Thoratec Heartmate II, Jarvik 2000, HeartAssist 5, Incor, and Synergy.

(H) Centrifugal pumps include HeartWare HVAD, DuraHeart, Levacor VAD, and EVAHEART LVAS.

(I) HeartMate II is the most studied LVAS and has recently gained FDA approval for bridge to transplant and destination therapy. Jarvik 2000, HeartAssist 5, HeartWare HVAD, DuraHeart, Levacor VAD, and EVAHEART LVAS currently have investigational trial exemption for bridge to transplant in the United States.

(J) The use of implantable devices for lifetime support (destination therapy) has increased significantly since approval of the HeartMate II in 2010. As the technology improves, complications decrease, and more candidates for permanent mechanical support are identified, we will see more patients with permanent VADs in almost all cardiology clinical settings.

II. PREOPERATIVE CONSIDERATIONS. Patient selection, preimplant considerations, and implant timing are critical in optimizing outcomes in patients receiving LVAS support.

A. Patient selection involves determining the appropriateness for mechanical circulatory support, operative mortality, and family/social support at discharge.
(1) Highest risk of mortality is prior to discharge from hospital.
(2) Trend at many large centers is to implant early to minimize or avoid progressive end-organ damage.
(3) Important preimplant medical factors include nutritional status, pulmonary vascular resistance, improve congestive hepatopathy and nephropathy, and optimize right heart function, candidacy for coagulation, underlying infections, and other end-organ dysfunction (renal, hepatic, and pulmonary).
(4) Other important preimplant factors include patient's social support system, psychosocial status, and the ability to care for the device itself.

B. Interagency Registry of Mechanically Assisted Circulatory Support (INTERMACS) patient profiles. INTERMACS is a registry designed to track patient selection, outcomes, and adverse events. Since inception, it has enrolled close to 6,000 patients and has provided key observations to improve patient selection and outcomes.
(1) INTERMACS (see Table 62.1) has defined patient profiles that highlight risk and timing of implantation.

TABLE 62.1 Interagency Registry of Mechanically Assisted Circulatory Support Patient Profile

Profile	Description	Comment
1	Critical cardiogenic shock	"Crash and burn profile." Definitive therapy is needed within hours. Has the lowest survival
2	Progressive decline on inotropic support	Inotropic-dependent patients. Progressive decline such as worsening renal function, nutritional status, or volume status despite increased inotropic support. Definitive therapy is needed within days
3	Stable but not inotrope dependent	Stable on lower doses of inotropes, but unable to wean. Stable volume status, organ function, and nutrition, but inotropic dependent. Elective therapy may be needed within weeks to a few months. Profile 3 has the best outcomes
4	Resting symptoms home on oral therapy	Patients have daily symptoms requiring fluctuating high-level doses of diuretics. Elective therapy may be needed within weeks to a few months. Outcomes for this level are under investigation for appropriateness
5	Exertion intolerant	Evidence of refractory volume-overloaded state. Able to perform ADLs and comfortable at rest, but have refractory symptoms with exertion or in a persistently volume-overloaded state. Patients in INTERMACS level 4 may overlap with this profile. Outcomes for this level are under investigation for appropriateness
6	Exertion limited	No evidence of refractory volume-overloaded state. Able to perform ADLs and comfortable at rest. Limited by symptoms within minutes of meaningful activity. Outcomes for this level are under investigation for appropriateness
7	Advanced NYHA class III symptoms	Transplantation or mechanical circulatory support is not currently indicated in this profile

ADLs, activities of daily living; INTERMACS, Interagency Registry of Mechanically Assisted Circulatory Support; NYHA, New York Heart Association.

III. TERMS AND BASIC MECHANICS OF LVASs. Basic terms, mechanics, and physiology are outlined in this section. When evaluating a patient with LVAS, no single parameter should be used for diagnosis.

- **A. Basic mechanism.** Volume of flow is determined by the speed of the rotary impeller and the change of pressure across the pump. At a fixed speed, flow is inversely related to pressure. Thus, when the pump pressure increases, the flow will decrease at a fixed speed.
- **B. Pump differential pressure** is equal to the aortic pressure minus the left ventricular (LV) pressure. Since the aortic pressure typically remains unchanged within a normal range, the change in pump differential pressure is primarily dependent on the LV pressure.
- **C. Pump speed** is a direct measurement of the rotational velocity. Continuous-flow ventricular assist system operates at a fixed pump speed. The optimal pump speed is typically determined by a ramp study (see Section **IV**). Substantial changes in pump speed are usually associated with abnormal conditions. Abrupt drops in pump speed followed by normalization may indicate suction events (see below).
- **D. Pump power** is a direct measure of motor voltage and current (power = current voltage difference). Pump speed, flow, and demand directly affect power. Gradual or sudden sustained increases in power may signify thrombus or debris accumulation in the motor.
- **E. Pump flow** is a calculated measurement that essentially maintains a linear relationship with power at a given speed. Within normal ranges, increased power results in increased flow. However, inherent to being a calculated value, pump flows may become unreliable at the low and high extremes of the flow–power relationship. For example, a thrombus may cause an abrupt increase in power and an incorrect calculation of increased flow. Suction events may also lead to incorrect flow values. Thus, in a given clinical situation, further assessment of pump function is required.
- **F. Pulsatility index (PI)** is the averaged measure of the magnitude of flow pulses over a 15-second interval. Flow pulses are determined by the contractile function of the left ventricle that produces changes in ventricular pressure. Higher PI values (range 1 to 10+) indicate greater LV contribution (filling and contractility), whereas lower PI values represent greater mechanical pump contribution. While the patient is at rest, there should be little change in the PI. Decreased PI may represent underfilling due to a change in contractile function or hypovolemia.
- **G. Suction event** occurs when the LV pressure becomes so negative that the left ventricle collapses.

IV. RAMPED SPEED STUDY. This is a method used to determine the speed that is the safest for the patient and provides the optimal LVAS support. Optimal speed is achieved when cardiac index, septum position, and LV dimensions are within normal ranges.

- **A. Initial optimum speed** is determined ideally while still in the operating room with transesophageal echocardiography.
- **B.** Ramped speed studies are best performed on hemodynamically stable, euvolemic patients and may use transthoracic echocardiography.
- **C.** Evaluation can be performed with echocardiography or invasive hemodynamics.
- **D.** Determination of **low fixed speed** is achieved by gradually decreasing the pump speed until the patient becomes symptomatic and the aortic valve opens with every beat when cardiac index falls below 2.5 L/min/m^2 or pulmonary vascular resistance begins to increase. For the HeartMate II, speed should never go below 8,000 rpm. At the low fixed speed, record the LV diameter, septal position, patient vitals, and, if available, hemodynamics.
- **E.** Determination of **high fixed speed** is achieved by increasing the rotational velocity of the pump until there is intraventricular flattening by echocardiography

(parasternal long or four-chamber view). At the high fixed speed, record the LV diameter, frequency of the aortic valve opening, patient vitals, and, if available, hemodynamics.

F. Determination of the **optimum fixed speed** is typically the median of the low fixed speed and high fixed speed. However, this speed should be adjusted based on clinical judgment as well as the desired frequency of aortic valve openings. It is also recommended that the pump speed is at least 400 rpm below the high fixed speed.

V. PUMP PARAMETER ABNORMALITIES

A. Pump speed

(1) Large speed changes in fixed speed mode are abnormal.

(2) A suction event has two phases of pump speed change: initial decrease to lower limit at the beginning of the suction event followed by a gradual increase to fixed speed at the end of the suction event.

(3) In the absence of suction events, consider primary pump or control issues.

B. Pump power

(1) Normal changes in power may be due to increased flow and demand or change in speed.

(2) Abrupt increases in power may be associated with pump thrombus.

(3) Gradual increases in power may be associated with in situ formation of bearing thrombus or bearing deposition.

C. Pump flow

(1) Flow is the calculated value based on pump speed and power. It becomes an imprecise estimation at extremely high and low values.

(2) Changes in flows should be used in parallel with other device and clinical parameters.

(3) During pump or bearing thrombus events, pump flow will be abnormally elevated.

D. Pulsatility index

(1) Under normal conditions, PI can increase with increased preload and LV contractility.

(2) Decreases in PI typically warrant further investigation as this may represent hypovolemia, obstruction of the inflow or outflow tract, or thrombus.

VI. DEVICE COMPLICATIONS

A. Suction event

1. Signs: Arrhythmias (ventricular tachycardia) and hypotension.

2. Parameter changes: In the HeartMate II, speed automatically decreases to low fixed speed followed by slow increase to set speed. Pump flow decreases.

3. Management: Chest radiograph to assess inflow cannula position. Assess volume status to rule out hypovolemia and assess right ventricular (RV) function. Consider decreasing pump speed with ramped speed study.

B. Inflow tract obstruction

1. Signs: New-onset HF symptoms, arrhythmias, and hemolysis.

2. Parameter changes: Increased pump power, decreased pump flow, and PI. High velocities across inflow by Doppler echocardiography.

3. Management: Consider reducing speed if septal obstruction is noted on ramped speed study. Chest radiography to assess inlet position (supine and upright). Echocardiography for tamponade and right heart function. Computed tomography scan to assess inflow cannula position.

C. Outflow tract obstruction

1. Signs: New-onset HF symptoms and hemolysis.

2. Parameter changes: Increased pump power, decreased pump flow, and PI.

3. Management: Ramped speed study looking for changes in LV dimension and in diastolic arterial pressures with speed changes. Echocardiography and angiography for outlet position and the presence of graft kink.

D. Deposition of thrombus

1. Signs: New-onset HF symptoms, hemolysis, change in pump sound with auscultation, and hypotension with increased pulse pressure.
2. Parameter changes: Increased pump power, pump flow, and decreased PI.
3. Management: Angiography and echocardiography to assess pump flow. Heparin may slow progression of thrombus formation. Consider thrombolytics (rarely). Consider pump replacement.

E. Mechanical pump failure

1. Signs: New-onset HF symptoms, vibration of pump, and hypotension with increased pulse pressure.
2. Parameter changes: Cannot maintain pump speed, PI > 10, and multiple red heart alarms.
3. Management: Contact surgeon. Consider replacement of pump.

VII. SPECIFIC CLINICAL SCENARIOS FOR PATIENTS WITH LEFT VENTRICULAR ASSIST DEVICE (LVAD)

Diagnosis and management of clinical changes in patients with LVAD should include, when appropriate, physical examination and multimodality imaging: echocardiography, computed tomography, radiography, and invasive hemodynamics.

A. Hypovolemia

1. Signs: Hypotension and possible suction events causing syncope or arrhythmias.
2. Echocardiography may demonstrate decreased RV and LV dimensions.
3. Parameter changes encountered: Decreased PI.
4. Suggested management: Consider adjustment of diuretics, decreasing pump speed, and volume expansion.

B. RV failure

1. Signs: Hypotension, possible suction events causing syncope or arrhythmias, and return of HF symptoms.
2. Echocardiography may demonstrate decreased RV function and enlarged RV dimensions.
3. Parameter changes encountered: Decreased pump flow and pump speed below fixed speed.
4. Suggested management: Consider inotropes, pulmonary vasodilators, volume expansion, ramped speed study, and mechanical right ventricular assist device.

C. Tamponade

1. Signs: Hypotension and decreased postoperative chest tube drainage.
2. Echocardiography may demonstrate focal or circumferential effusion causing tamponade physiology.
3. Parameter changes encountered: Decreased pump flow.
4. Suggested management: Pericardiocentesis or exploratory thoracotomy.

D. Hypertension

1. Signs: Typically asymptomatic.
2. Parameter changes encountered: Decreased pump flow and pump power and increased PI.
3. Suggested management: Increased afterload reduction and diuretics.

E. Volume overload

1. Signs: Edema.
2. Echocardiography to assess ventricular and valvular function.
3. Parameter changes encountered: Increased pump flow, pump power, and PI.
4. Suggested management: Consider adjustment of diuretics, fluid restriction, and ramped speed study.

F. Recurrent HF

1. Signs: Hypotension, pulmonary edema, and low cardiac index.
2. Echocardiography may demonstrate decreased RV and/or LV function. Valvular function should be assessed.
3. Parameter changes encountered: Decreased pump flow and PI.
4. Suggested management: Ramped speed study, adjustment of diuretics, RV function assessment, invasive hemodynamics, and treatment of HF symptoms.

G. Aortic insufficiency

1. Signs: Hypotension and return of HF symptoms.
2. Echocardiography shows dilated LV with severe aortic insufficiency.
3. Parameter changes: Increased pump flow with dilated LV.
4. Suggested management: Decrease pump speed to decrease the amount of aortic insufficiency. May eventually need aortic valve surgery.

H. Arrhythmia

1. Signs: Ventricular tachycardia on electrocardiogram, Holter, or telemetry. Syncope or presyncope.
2. Echocardiography may demonstrate intermittent suction events, worsened LV or RV function, and new valvulopathy.
3. Parameter changes: Decreased pump flow, pump power, and PI.
4. Suggested management: Ramped speed study and assess inflow cannula to ensure proper placement.

CHAPTER 63

Olcay Aksoy

Intraaortic Balloon Counterpulsation

I. INTRODUCTION. Intraaortic balloon counterpulsation (IABC) is usually used to **support hemodynamics** in cardiogenic shock and to **relieve medically refractory ischemia** in patients with severe coronary disease. The duration of support with an intraaortic balloon pump (IABP) is typically short, because multiple complications can develop in patients treated with IABC. Patients should be carefully selected for receiving IABC therapy and should be closely monitored in a critical care setting while the IABP is in place.

II. INDICATIONS

A. Cardiogenic shock

1. **Bridge to revascularization.** IABC provides temporary hemodynamic stabilization in patients with cardiogenic shock caused by acute myocardial infarction (MI). Hospital survival rates for cardiogenic shock with balloon pump support alone without revascularization are poor (5% to 20%). Early revascularization with percutaneous transluminal coronary angioplasty (PTCA) improves survival rates in cardiogenic shock caused by acute MI.
   a. In the **Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries I (GUSTO I)** trial comparing fibrinolytic regimens for acute ST-segment elevation myocardial infarction (STEMI), PTCA was the only factor associated with a lower 30-day mortality rate in 2,972 patients with cardiogenic shock.
   b. In addition, early placement of an IABP in this cohort of patients was associated with lower 30-day and 1-year mortality rates.
   c. Cardiogenic shock and hemodynamic support during or after percutaneous coronary intervention are the primary reasons for IABP placement in more than half of all patients treated with IABC. IABP placement is an **ACC/AHA class I** recommendation in patients with STEMI presenting with cardiogenic shock when shock is not quickly reversed with pharmacologic therapy. The IABP in this setting is a stabilizing measure for angiography and prompt revascularization.
2. **Bridge to a tertiary center.** Thrombolytic therapy alone in patients with cardiogenic shock is less successful than mechanical reperfusion. However, the addition of IABC to thrombolysis can improve outcomes in patients with cardiogenic shock. In 46 patients with acute MI and cardiogenic shock treated at community hospitals without angioplasty capabilities, simultaneous treatment with thrombolysis and IABC was associated with an improved 1-year survival rate (67% vs. 32%) and successful transfer to a tertiary facility for revascularization when thrombolysis failed.

B. Acute MI treated with catheter-based reperfusion.

The **benefits** of IABC in patients with acute MI without cardiogenic shock treated with catheter-based reperfusion are **uncertain.**

1. In a randomized trial of 182 hemodynamically stable patients who underwent direct PTCA for acute MI, prophylactic IABC for 2 days after the procedure

reduced recurrent ischemia and reocclusion of the infarct-related artery but had no effect on survival or reinfarction.

2. In the **Primary Angioplasty in Myocardial Infarction II (PAMI II)** trial, 437 high-risk patients (age > 70 years, multivessel coronary disease, reduced ejection fraction, vein graft disease, or persistent ventricular arrhythmias) treated with direct PTCA for acute MI were randomized to ±1 to 2 days of IABC after PTCA. Patients treated with IABC had a slight reduction in recurrent ischemia but had no reduction in mortality, reinfarction, or infarct-related artery reocclusion. Thus, hemodynamically stable patients with acute MI treated with catheter-based reperfusion are not likely to benefit from IABP support after the intervention.

C. High-risk percutaneous revascularization. Patients at high risk for complications during percutaneous revascularization include those with unprotected left main coronary disease, left ventricular dysfunction (ejection fraction < 40%), the target vessel supplying > 40% of the myocardial territory, or severe congestive heart failure (CHF). Placement of an IABP in these high-risk patients affords the operator a longer duration of ischemia during balloon inflation and wire manipulation.

1. In a study of 219 patients undergoing unprotected left main trunk stenting, elective IABP placement was associated with fewer intraprocedural major adverse cardiac events, including combined end points of severe hypotension, MI, need for urgent bypass surgery, and death.
2. Although there are no specific recommendations for when to use IABC during high-risk coronary interventions, improved percutaneous revascularization techniques with coronary stents and adjunctive glycoprotein IIb/IIIa receptor antagonists have reduced the need for prophylactic IABP placement in high-risk patients.

D. Mechanical complications of acute MI. **Acute mitral regurgitation (MR)** and **ventricular septal defect** are devastating complications of acute MI and frequently cause rapid deterioration progressing to cardiogenic shock. An IABP should be placed before surgical repair in patients with hemodynamically significant MR or ventricular septal defect after an MI. Placement of an IABP in the setting of STEMI and secondary acute mitral valve regurgitation is an **ACC/AHA class I** indication. Similarly, insertion of an IABP and prompt surgical referral are **class I** recommendations.

E. Refractory unstable angina. Patients with severe coronary disease who have refractory ischemia or hemodynamic instability show **dramatic improvement** when IABC is used before revascularization. The ACC/AHA clinical guidelines assign a **class I** recommendation in STEMI patients and a **class IIa** recommendation in Unstable angina/Non ST segment elevation myocardial infarct (UA/NSTEMI) patients for IABP placement in the setting of severe ischemia that is continuing or recurs frequently despite intensive medical therapy. In the setting of STEMI, refractory pulmonary congestion carries a **class IIb** recommendation for IABP placement.

F. Weaning from cardiopulmonary bypass/postoperative pump failure. Patients with severe left ventricular dysfunction or those with prolonged runs on cardiopulmonary bypass can be difficult to wean from bypass after open heart surgery because of stunned myocardium from prolonged cardioplegic arrest. For these patients, IABP support improves hemodynamics and facilitates weaning from cardiopulmonary bypass.

G. End-stage cardiomyopathy/bridge to cardiac transplantation. An IABP improves cardiac output and lowers filling pressures in patients with dilated and ischemic cardiomyopathy. It can be used for hemodynamic support before cardiac transplantation.

1. **Disadvantages** of prolonged IABP support in patients awaiting cardiac transplantation include a high risk of infection and the need for continuous bed rest.
2. However, with improved inotropic therapy and implantable left ventricular assist devices for patients awaiting cardiac transplantation, IABC is now used infrequently for prolonged mechanical support in patients with end-stage cardiomyopathy.

H. **Refractory ventricular arrhythmias.** Incessant ventricular tachycardia compromises left ventricular filling, reduces stroke volume, and causes or exacerbates ischemia. IABC improved hemodynamics, lessened ischemia, and controlled refractory ventricular arrhythmias in 86% of patients in a large case series. Placement of an IABP support in patients with STEMI and refractory polymorphic ventricular tachycardia carries an **ACC/AHA class IIa** recommendation.

I. **Support during noncardiac surgery.** Patients with severe coronary disease, recent MI, and severe left ventricular dysfunction are at high risk for cardiac complications when they undergo noncardiac surgery. Case reports have demonstrated that high-risk patients are stabilized hemodynamically and have acceptable postoperative outcomes when prophylactic IABP support is used during and after noncardiac surgical procedures.

J. **Decompensated aortic stenosis** can be managed with temporary IABP support to improve the stroke volume and reduce the transvalvular gradient before aortic valve replacement. In a study of 25 patients with severe aortic stenosis and cardiogenic shock, IABP support was associated with prompt improvement in cardiac output and filling pressures, allowing stabilization of patients before surgery. However, because aortic insufficiency often accompanies severe aortic stenosis, careful monitoring early after initiation of IABC is recommended to ensure that aortic insufficiency is not worsened by the balloon pump.

III. CONTRAINDICATIONS

A. **Aortic dissection.** Any type of aortic dissection precludes IABP use because of the potential of the balloon catheter to extend the dissection and to worsen ischemia of a peripheral vascular bed that may be involved by the dissection.

B. **Abdominal or thoracic aneurysm.** Using IABP with an abdominal or thoracic aneurysm can precipitate an acute aortic dissection, dislodgement of atheroemboli, or aortic rupture, so the presence of an aneurysm is a contraindication to IABP use.

C. **Severe peripheral vascular disease**

1. The majority of the complications of IABC are caused by vascular insufficiency in the accessed leg because of the **large size of the balloon sheath and catheter and the concomitant presence of peripheral vascular disease** in patients who typically need IABC. In the past, the IABP catheters had been available only in 8F and 9.5F sizes; however, with improving equipment, 7F catheters have been introduced, and these have diminished the rate of complications due to obstruction of arterial flow.
2. **Limb ischemia and threatened limb viability** can occur when peripheral perfusion is compromised by the balloon catheter and sheath. The IABP catheter can be inserted without a sheath to reduce the diameter of obstruction in the iliac vessels, but in patients with tortuous aortoiliac vessels, sheathless IABP insertion can be difficult.
3. Thus, severe peripheral vascular disease is a contraindication to IABP insertion, depending on the necessity of IABP support and the degree of vascular compromise.

D. **Descending aortic and peripheral vascular grafts**

1. **Prosthetic descending aortic grafts and iliofemoral vascular grafts** are relative contraindications to IABC. Consultation with a vascular surgeon is recommended before attempting balloon pump insertion in these patients.
2. **Iliac artery stents** are not an absolute contraindication to IABP placement. However, passage of the guidewire and balloon catheter through the stent must be performed under direct fluoroscopic guidance.

E. **Coagulopathy or contraindication to heparin**

1. The balloon catheter is thrombogenic, and intravenous heparin is commonly given while the IABP is in place to prevent the development of thrombi on the balloon surface. Patients with a contraindication to heparin, such as those with prior heparin-induced thrombocytopenia, can be **anticoagulated with alternative agents** such as direct thrombin inhibitors like bivalirudin.

2. After cardiac surgery, heparin can be avoided because of the increased risk of intrathoracic bleeding, but IABP support in such patients is usually of short duration. In nonsurgical patients, if an anticoagulant cannot be given or if a severe coagulopathy exists that could precipitate bleeding at the access site, IABC is discouraged, but it could safely be undertaken for a short period.

F. Moderate to severe aortic insufficiency. By inflating during diastole, the IABP can worsen aortic insufficiency when blood is displaced to the proximal aorta. No consensus exists as to what degree of aortic insufficiency absolutely contraindicates IABP use. Therefore, **careful monitoring** of patients with aortic insufficiency who absolutely need IABP support is recommended.

IV. HEMODYNAMICS OF BALLOON PUMP FUNCTION

A. Decreased afterload

1. As systole begins, the intraaortic balloon rapidly deflates and creates a negative pressure in the aorta, which reduces afterload and improves forward flow from the left ventricle. Afterload reduction occurs because the aortic end-diastolic pressure is reduced, resulting in an increase in cardiac output of approximately 20% and a decrease in the mean pulmonary capillary wedge pressure of approximately 20%.
2. The **overall hemodynamic benefit** of IABP appears to be a reduction in left ventricular wall stress from decreased filling pressures and decreased afterload, which in turn improves stroke volume and cardiac output (see Figs. 63.1 and 63.2).

B. Augmented coronary perfusion

1. When the balloon inflates during diastole, it displaces blood to the proximal aorta and augments aortic diastolic pressure and, thus, coronary perfusion pressure. The augmentation of coronary perfusion pressure is more dramatic when systemic hypotension is present (see Figs. 63.1 and 63.2).

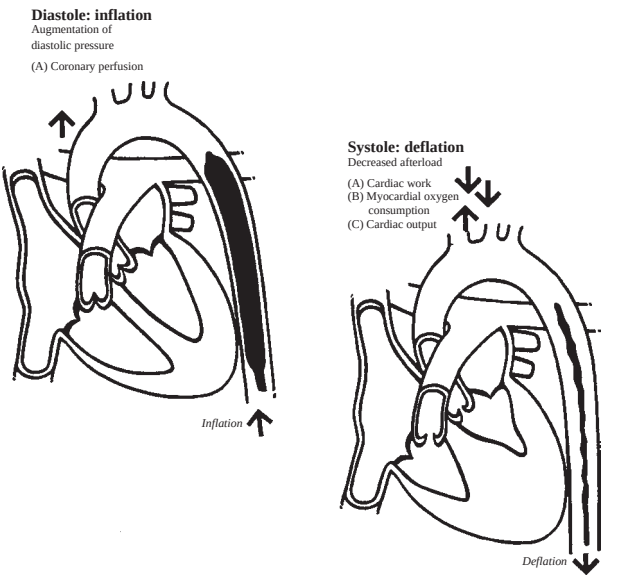

FIGURE 63.1 By inflating during diastole, the intraaortic balloon pump increases coronary perfusion. Deflation of the balloon at the onset of systole decreases myocardial wall stress and oxygen demand and increases cardiac output. Courtesy of Datascope Corp.

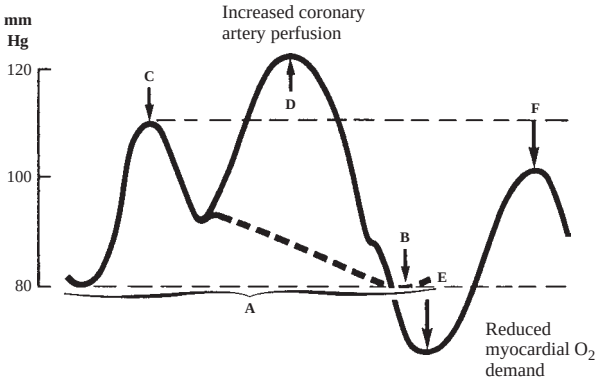

(A) One completed cardiac cycle
(B) Unassisted aortic end-diastolic pressure
(C) Unassisted systolic pressure
(D) Diastolic augmentation
(E) Assisted aortic end-diastolic pressure
(F) Reduced systolic pressure

FIGURE 63.2 Proper timing of balloon function occurs when the balloon inflates on the downslope of the systolic pressure waveform and deflates before the onset of the next systolic waveform. The intraaortic balloon pump inflation in diastole increases diastolic pressure to improve coronary artery perfusion and to increase mean arterial pressure. In addition, aortic end-diastolic pressure is reduced when the balloon deflates in end-diastole to lower afterload and myocardial oxygen demand than through increased coronary perfusion. Courtesy of Datascope Corp.

2. Doppler flow studies have demonstrated that peak coronary flow velocity is increased with IABP support, but there is no improvement in coronary flow past critical coronary stenoses (unless the obstructions are first relieved with percutaneous revascularization). Also, collateral coronary flow does not increase with IABP support. Thus, with severe, nonrevascularized coronary disease, IABP relieves ischemia more through decreased left ventricular wall stress and decreased myocardial oxygen demand than through increased coronary perfusion.

V. INSERTION TECHNIQUE/PATIENT EVALUATION AND MONITORING

A. Balloon sizing is based on the patient's height. Four common balloon sizes are available: 50 cm^3 for patients taller than 6′, 40 cm^3 for patients between 5′ 4″ and 6′, 34 cm^3 for patients between 5′ and 5′ 4″, and 25 cm^3 for patients shorter than 5′. Balloon length and diameter increase with each larger size. The 40-cm^3 balloon is most commonly used, whereas the 50-cm^3 balloon is rarely used because the balloon is too long for most patients.

B. Evaluating peripheral vasculature. Proximal and distal pulses are assessed in both legs, and ankle/brachial indices can also be determined. The leg with the strongest pulses and/or the best ankle/brachial index score should be chosen for access.

C. Insertion technique

1. **Gaining access/sheath insertion.** After careful evaluation of clotting parameters and peripheral vasculature, the leg chosen for access should be shaved and prepped with antiseptic solution from the umbilicus to the knee. After infiltration with a local anesthetic, the femoral artery is accessed with an 18G introducer needle, and a 0.030″ × 145 cm J-tipped guidewire is advanced through the needle to the aortic arch under **fluoroscopic guidance**. A smaller 5F dilator

is first inserted over the wire to dilate the subcutaneous tissues. Then the sheath, loaded with a larger dilator that is 1F smaller than the sheath, is inserted over the guidewire. The guidewire should be left in place in the aortic arch.

2. **Balloon insertion.** The two commonly available balloon catheter sizes are 8F and 9.5F. A 7F- and 7.5F-sized catheter and sheath have become available but pertinent data regarding their use are still limited. The prewrapped balloon is inserted over the guidewire and is advanced until the proximal tip is positioned 1 cm below the left subclavian artery and 2 cm above the carina. The guidewire is then removed, and the distal tip of the balloon is visualized under fluoroscopic guidance to ensure that it is out of the sheath.
3. **Insertion without fluoroscopy guidance.** Fluoroscopic guidance is recommended for placement of the IABP. However, if fluoroscopy is unavailable, the distance from the angle of Louis to the umbilicus and then to the common femoral artery insertion site is measured to determine the approximate distance the balloon must be advanced.
4. **Surgical insertion**
   a. Occasionally, balloon pumps can be inserted surgically **by directly exposing the common femoral artery** or by suturing a 6- to 12-mm prosthetic graft end-to-side to the femoral artery to provide a conduit for the catheter. Distal limb ischemia is reduced with these methods, but grafts must be removed surgically, and the femoral artery has to be directly repaired after IABP removal when surgical access is used.
   b. Balloon pumps can also be directly inserted into the ascending or thoracic aorta **during open heart surgery**.
5. **Difficulties with access.** If passage of the guidewire is difficult, a 5F sheath can be placed in the common femoral artery. Then the contrast medium can be injected through the sheath or through a pigtail catheter to define the iliofemoral anatomy.
   a. If severe iliac or femoral artery obstruction is demonstrated, the balloon can be inserted on the contralateral side, the obstructions can be treated with peripheral angioplasty and stenting before balloon insertion, or the procedure can be aborted.
   b. If severe obstruction or aneurysmal dilatation of the distal abdominal aorta is demonstrated, the balloon catheter should not be inserted.
6. **Sheathless insertion.** In patients with peripheral vascular disease, the balloon catheter can be inserted without a sheath, directly over the guidewire, after appropriate dilatation of the subcutaneous tissue. Retrospective reviews have shown that lower limb ischemia is reduced with this technique. However, a sheathless balloon catheter cannot be repositioned once placed and has a greater potential to become infected from skin flora than a sheathed balloon catheter. Smaller balloon catheters and stiffer guidewires are being developed to aid in sheathless insertion.
7. **Tortuous iliofemoral vessels**
   a. When the tortuosity of the iliofemoral vessels prevents passage of the 0.030" guidewire supplied in the IABP kit, a 0.035" Wholey wire can be used to traverse the tortuous vessels. A long (45 or 60 cm) flexible sheath is then placed in the descending aorta past the tortuous iliac vessels.
   b. A superstiff 0.038" wire is then exchanged through the sheath. The 11" IABP sheath is inserted over the superstiff wire, which provides more support for placement of the less flexible IABP sheath. The superstiff wire is then exchanged for the 0.030" standard IABP wire through the sheath, and the balloon catheter is inserted over this wire into the proper position.

D. Initial setup

1. After insertion, the helium gas line of the balloon catheter is connected to the IABP console, and the central lumen of the catheter is attached to an arterial pressure monitor device on the console with pressure tubing, after allowing the line to backbleed.
2. Balloon autoinflation is initiated from the console, the arterial line attached to the central lumen of the catheter is flushed, and the initial IABP inflation is at 1:2 (per cardiac cycle) while the timing is adjusted (Section **VI**).

3. Balloon inflation is then observed under fluoroscopic guidance to ensure that the balloon is completely out of the sheath. If the balloon is kinked or is not inflating fully, it should be repositioned by pulling the sheath back a few inches or it should be manually inflated.
4. Finally, the sheath and balloon catheter are sutured in place, dressed using sterile technique, and the inflation is changed to 1:1.

E. Monitoring

1. **A chest x-ray film is immediately obtained** after IABP placement to verify the catheter position, even if fluoroscopic guidance has been used.
2. **Intravenous heparin** is started once the balloon and sheath are secure to maintain the activated partial thromboplastin time at 50 to 70 seconds.
3. **Daily chest x-ray films** are recommended while the IABP is in place so that the physician can check the position of the catheter. If the catheter needs to be repositioned, it can be manipulated through a sterile plastic sleeve placed over the part of the catheter that extrudes from the sheath while the balloon is placed on standby mode.
4. Daily hemoglobin and platelet counts are followed to monitor for hemolysis and thrombocytopenia.

F. Care of the patient with an IABP

1. All patients with an IABP in place should be closely observed in a **critical care setting. The patient should be kept supine in bed,** and peripheral pulses should be regularly evaluated for **possible limb ischemia** (dorsalis pedis/posterior tibial pulses should be checked every 6 to 8 hours with use of Doppler if necessary).
2. **The accessed leg should be secured** to prevent inadvertent or involuntary movement by the patient.
3. **Use of prophylactic antibiotics is not recommended** while the IABP is in place.
4. **Blood samples generally should not be obtained from the central lumen of the IABP** because the risk of clotting the lumen is increased, and air or small thrombi can be injected through the central lumen during flushing of the tubing after blood withdrawal.

VI. BALLOON PUMP TRIGGERING AND TIMING

A. Triggering. Balloon pump inflation can be triggered by the surface electrocardiogram (ECG), the arterial pressure waveform, a paced rhythm, or an internal asynchronous mode.

1. Preferably, the surface ECG is used to trigger IABP inflation, which is appropriately delayed after the R wave to begin at the time in the cardiac cycle when the aortic valve closes (dicrotic notch).
2. If the IABP fails to trigger properly from the surface ECG, change the lead being evaluated, check surface electrode placement, or increase the QRS gain on the console monitor.
3. For patients with poor surface electrocardiographic tracings, the balloon can be triggered from the central arterial pressure waveform. Pacing spikes should be used to trigger the balloon in patients who are 100% paced.
4. When the patient is arresting or when the other triggering mechanisms are not working correctly, an internal asynchronous mode can be used to trigger the balloon to inflate at a regular interval.

B. Timing. Ideal balloon pump timing occurs when the balloon inflates on the downslope of the systolic pressure waveform before the dicrotic notch and deflates before the onset of the next systolic pressure waveform (see Fig. 63.2). Timing is usually adjusted manually, but it can be automatically adjusted by internal algorithms programmed in the console.

1. **Early inflation** (see Fig. 63.3) is defined as inflation of the IABP before aortic valve closure (dicrotic notch).

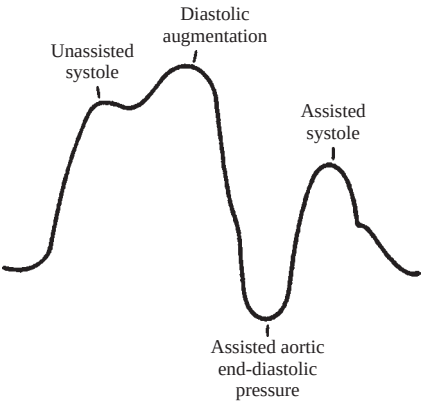

FIGURE 63.3 With early balloon inflation, the aortic valve closes prematurely, and left ventricular wall stress and myocardial oxygen demand are increased. Courtesy of Datascope Corp.

   a. There is premature closure of the aortic valve with increased afterload, left ventricular wall stress, and myocardial oxygen demand. Stroke volume is decreased.
   b. It is corrected by delaying inflation until after aortic valve closure.
2. **Late inflation** (see Fig. 63.4) is defined as inflation of the IABP well after closure of the aortic valve.
   a. There is diminished diastolic pressure augmentation and suboptimal coronary perfusion.
   b. It is corrected by adjusting inflation to occur just before the dicrotic notch.
3. **Early deflation** (see Fig. 63.5) is defined as deflation of the IABP before isovolumic left ventricular contraction.
   a. There is suboptimal diastolic augmentation, coronary perfusion, and afterload reduction, which then lead to increased myocardial oxygen demand.
   b. It is corrected by delaying deflation until just before the onset of systole.
4. **Late deflation** (see Fig. 63.6) is defined as deflation of the IABP after the onset of systole.
   a. There is impaired left ventricular emptying, increased afterload and preload, increased myocardial oxygen consumption, and reduced stroke volume.
   b. It is corrected by adjusting deflation to occur just before the onset of systole.

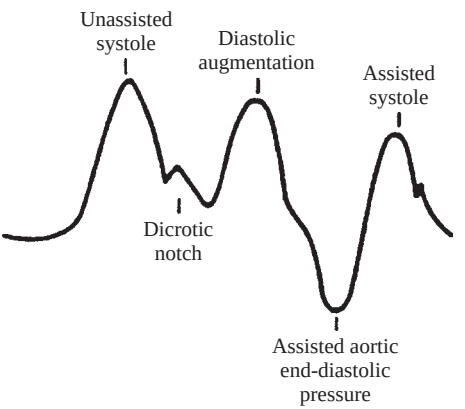

FIGURE 63.4 With late balloon inflation, there is suboptimal augmentation of diastolic aortic pressure and coronary perfusion. Courtesy of Datascope Corp.

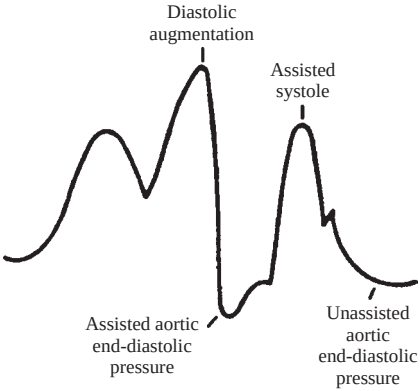

FIGURE 63.5 With early balloon deflation, there is suboptimal augmentation of coronary perfusion and afterload reduction. Courtesy of Datascope Corp.

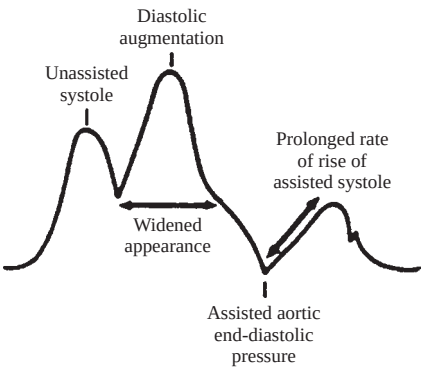

FIGURE 63.6 With late balloon deflation, there is no afterload reduction, and myocardial oxygen consumption is increased. Courtesy of Datascope Corp.

5. **During arrhythmias.** Adequate augmentation with the balloon pump is difficult to achieve with tachyarrhythmias. When heart rate approaches 150 beats/min, there is insufficient time for the helium gas to shuttle in and out of the balloon with each inflation. With rapid atrial fibrillation, variable systolic pressure waveforms caused by inadequate left ventricular filling and rapid pulse rates make augmentation especially difficult. Adjusting balloon inflation to 1:2 can sometimes improve augmentation with tachyarrhythmias.

C. Troubleshooting. In the situation of **console alarms**, there may be the following problems:

1. **Loose connections** in the gas drive line or arterial pressure tubing.
2. **Blood in the tubing.** If blood is detected in the gas drive lumen, put the balloon catheter on standby and evaluate for balloon rupture or entrapment (Section **VII**).
3. **Poor augmentation**
   - **a.** Adjust the timing.
   - **b.** Change the triggering mechanism (Section **VI.A**).
   - **c.** Evaluate inflation/deflation of the balloon and the catheter position under fluoroscopic guidance to detect balloon kinking.
   - **d.** If the IABP is thought to be positioned in a false lumen of the aorta because of poor augmentation, 10 to 20 mL of contrast media can be injected through the central lumen of the catheter to evaluate the position under fluoroscopy.

VII. COMPLICATIONS

A. Vascular. Common vascular complications of IABP include limb ischemia, hematoma around the access site, and bleeding from the access site. Rates of vascular complications have varied in the literature from 5% to 20%, depending on the patient populations studied. However, a contemporary series showed the incidence of limb ischemia to be 2.3% and incidence of major limb ischemia to be 0.5% in 5,495 consecutive patients with IABP. Diabetes, female sex, preexisting peripheral vascular disease, history of smoking, and catheter size are all independent risk factors that are strongly associated with the development of ischemic vascular complications from IABP use.

1. **Ischemia**
   - **a.** If ischemia develops in the accessed leg, the balloon catheter and sheath should be removed and hemostasis obtained at the access site.
   - **b.** If ischemia is still present, consultation with a vascular surgeon is indicated. Surgical intervention for ischemic limbs caused by IABP catheters includes thrombectomy, surgical bypass grafting, and, rarely, amputation.
2. **Bleeding**
   - **a.** Bleeding around the access site develops in 1% to 5% of patients treated with IABP. It is usually controlled with prolonged manual pressure at the access site.
   - **b.** Hematomas that develop at the access site may require transfusion of blood products and, occasionally, direct arterial repair.
   - **c.** Pseudoaneurysms after IABP removal are rare but often require surgical correction.

B. Infection. Infectious complications are rare and include access site infections, catheter infections, and bacteremia. No studies have addressed how frequently balloon catheters become infected and how frequently they need to be changed to limit infectious complications.

C. Balloon rupture should be considered if blood is detected in the gas drive line lumen or if balloon augmentation ceases.

1. Small leaks in the balloon can develop from damage to the balloon surface caused by inflation against calcified aortic plaques. Rates of balloon leak can be as high as 4.2%.
2. *Potential complications for the patient include helium gas embolism and balloon entrapment when blood leaks into the balloon, clots, and prevents adequate deflation of the balloon for removal.*
3. Use of standard-sized balloons (40 cm^3) in patients shorter than 170 cm (5'6") is associated with balloon rupture. This is thought to be caused by damage to the balloon when inflation occurs in the smaller and more plaque-laden distal abdominal aorta. Thus, a 34-cm^3 balloon should be used in patients shorter than 170 cm.

D. Balloon entrapment occurs when balloon rupture causes a clot to form within the balloon, preventing deflation during removal. When resistance is encountered during balloon catheter removal, balloon entrapment should be considered and fluoroscopy immediately carried out to assess the position of the retained catheter.

1. Management of balloon entrapment usually involves surgical extraction because forceful removal of a partially deflated balloon catheter could cause serious vascular injury.
2. Case reports have documented successful lysis of clots within the balloon by instilling thrombolytic agents through the gas drive lumen of the IABP catheter. The balloons were deflated after clot lysis and the catheters successfully removed.

E. Red blood cell and platelet destruction. Due to the shear forces of the balloon catheter, hemolytic anemia and mild thrombocytopenia can occur during IABP support. Daily hemoglobin and platelet values should be checked. Platelet counts < 50,000 are unlikely to be caused by the IABP and alternative causes should be sought.

F. Other complications. Rare complications of IABP use include acute renal failure, mesenteric ischemia, and paraplegia from plaque embolization leading to

thrombosis of the renal, mesenteric, or spinal arteries, respectively. Aortic dissections and aortic perforations, though rare, usually occur during insertion.

VIII. REMOVING THE IABP CATHETER

A. Weaning. Whether IABC needs to be weaned before the balloon catheter is removed depends on multiple factors, including the duration of the support, the hemodynamic status of the patient, and left ventricular function.

1. The usual practice is to change IABP inflation to 1:2 for a few hours and then to 1:3 with close hemodynamic monitoring.
2. At the same time, intravenous inotropic drugs are used to simulate the IABP's hemodynamic effects. Dobutamine or milrinone is used to maintain an adequate cardiac output, and nitroprusside is used to replace the afterload reduction provided by the IABP.
3. If weaning is tolerated hemodynamically, the balloon can then be removed.

B. Withdrawal of the balloon catheter and sheath

1. Intravenous heparin should be discontinued for at least 4 hours before removal of the catheter. The activated coagulation time is checked until it falls below 150 seconds or partial thromboplastin time normalized.
2. Percutaneously placed catheters can then be removed manually, but surgically placed catheters must be removed with direct arterial repair.
3. To begin removal of the balloon catheter, the balloon is changed to standby and the gas drive line is disconnected. Then, the balloon catheter is pulled back until resistance is met, indicating that the catheter is in the sheath. The sheath and the balloon catheter are then withdrawn together as a unit, but excessive force should never be applied.

C. Hemostasis

1. After the balloon is withdrawn, the puncture site is allowed to backbleed for 1 to 2 seconds while pressure is held distal to the puncture site to evacuate proximal thrombi.
2. Then manual pressure is applied proximal to the puncture site, and backbleeding is repeated to evacuate distal thrombi.
3. Manual pressure is then applied for 30 to 45 minutes over the puncture site until adequate hemostasis is achieved.
4. A compressive dressing is applied thereafter.

D. Monitoring during IABP removal

1. During the application of manual pressure to the puncture site, the distal pulses in the leg should be continually assessed, and pressure should be adjusted to maintain adequate distal perfusion.
2. The patient should be confined to strict bed rest for 6 to 12 hours after the catheter and sheath have been removed, and the leg should be periodically assessed for signs of ischemia.

IX. CHANGING THE IABP CATHETER

A. Reasons for changing the IABP

1. When patients require prolonged IABP support, some clinicians change the catheter and sheath every 4 to 5 days to prevent infectious complications. However, there is no consensus on using this approach.
2. Other reasons for changing the IABP include balloon entrapment and rupture, kinking of the catheter or sheath (which prevents adequate balloon inflation), or fever (which may indicate bacteremia from a line infection).

B. Simultaneous change. In patients who are critically dependent on IABP support and who need the IABP changed for one of the above reasons, the catheter and sheath must be changed simultaneously with placement of a new IABP.

1. **Contralateral femoral artery**
   a. When the contralateral femoral artery can be used, it is accessed and the sheath is placed. A guidewire is then positioned in the aortic arch while the old balloon is on standby.
   b. Counterpulsation is reinitiated, and the new balloon catheter is prepared and readied for use.
   c. The old balloon is then deflated and quickly withdrawn, while the new balloon catheter is placed over the guidewire from the contralateral femoral artery. This technique limits the period without IABP support during the change to < 30 seconds.
   d. Anticoagulation can safely be discontinued before and after a simultaneous change to aid in achieving hemostasis at the old access site.
2. **Same femoral artery**
   a. When the contralateral femoral artery cannot be used, the old catheter and sheath must be removed and changed under direct vision.
   b. The accessed femoral artery is exposed surgically, and a purse-string suture is placed around the preexisting sheath.
   c. The old sheath is then removed, and tension is applied to the suture for hemostasis.
      (1) The small dilator in the catheter package is directly inserted into the previous puncture site, and the guidewire is advanced to the aortic arch through it.
      (2) The sheath is advanced over the guidewire into the proper position, and the purse-string suture is tied down.
      (3) The balloon catheter is then inserted via the sheath, and the soft tissue and skin incision are closed with sutures.
   d. In emergency situations, the preexisting sheath can be rewired and a new balloon catheter inserted through the old sheath. However, infectious complications are high with this approach.

CHAPTER 64

Andrew N. Rassi

Left Heart Catheterization

I. INTRODUCTION. In 1958, Dr. Mason Sones and colleagues at the Cleveland Clinic performed the first selective coronary arteriographic procedure. Since then, left heart catheterization (LHC) has become an important tool in diagnostic cardiology. More than 1.5 million cardiac catheterizations are performed yearly in the United States. Despite the advent of other imaging modalities, coronary arteriography remains the clinical gold standard for determining the presence of significant coronary artery disease (CAD).

LHC is an invasive procedure with serious potential risks. To be competent in LHC, a cardiologist-in-training must perform at least 300 catheterizations, serving as primary operator on 200. During training, the operator must be supervised by a cardiologist who is already competent in the procedure. Because there is the ability to treat a lesion with percutaneous intervention at the same time as the diagnostic angiogram, it is important to have a plan regarding how to use the information obtained.

II. INDICATIONS. The American College of Cardiology and the American Heart Association (ACC/AHA) have categorized reasonable indications for LHC as class I, when there is consensus that LHC is indicated, or class II, when there is no consensus that LHC is indicated, but nonetheless the procedure is frequently performed (see Table 64.1).

A. Acute myocardial infarction (MI). LHC is given a class I indication for routine use in acute MI, particularly in those who will likely undergo primary percutaneous cardiac intervention, those in cardiogenic shock or with other evidence of hemodynamic instability, or those with mechanical complications who are likely to undergo surgical repair. It can be used with the goal of performing primary angioplasty in patients with acute ST-segment elevation MI. There is evidence of the benefit of an early invasive strategy in stable patients with non–ST-segment elevation MI. In patients with non–ST-segment elevation MI, an early invasive strategy has received a class I indication in the presence of the following risk features: elevated cardiac troponins, new or presumed new ST-segment depression, heart failure (HF), depressed ventricular function, hemodynamic instability, sustained ventricular tachycardia, previous bypass surgery, and previous coronary intervention in the last 6 months. Patients with persistent pain or unresolved electrocardiographic changes after thrombolytic therapy are also class I candidates for LHC. Routine LHC soon after thrombolytic therapy in a patient who appears to have clinically reperfused is a class IIb indication.

B. Unstable angina. LHC is given a class I indication in the patient with refractory unstable angina that cannot be controlled by medical therapy. Its role in unstable angina that can be medically controlled is controversial.

C. Chronic stable angina. LHC is given a class I indication for purposes of revascularization in chronic stable angina for patients whose angina is poorly controlled by medicines or who are intolerant of antianginal medications.

D. Abnormal stress test. A stress test that is positive at a low work load (6.5 metabolic equivalents of oxygen consumption) or that is classified as high risk is a class I indication for LHC. An ST depression of 2 mm, especially in multiple leads or persisting into recovery 6 minutes, an ST elevation of 2 mm in leads without Q waves, a drop in blood pressure of > 10 mm Hg with exercise, or development of ventricular tachycardia with exercise constitutes a high-risk stress test. A high-risk stress test on a concomitant imaging modality showing left ventricle dilatation, a drop in ejection

TABLE 64.1 Indications and Contraindications to Left Heart Catheterization

Indications[a]	Contraindications[a]
- Acute myocardial infarction	- Active bleeding
- Unstable angina	- Coagulopathy
- Chronic stable angina, uncontrolled by medications	- Acute or chronic renal failure
- Abnormal stress test	- Active infection
- Ventricular arrhythmias	- Severe anemia
- Left ventricular dysfunction	- Electrolyte abnormalities
- Valvular heart disease	- Inability to lie supine (i.e., decompensated heart failure)
- Preoperative coronary assessment for cardiovascular surgery	- Malignant hypertension
- Preoperative risk assessment for noncardiovascular surgery	- Extensive comorbidities—risk of revascularization likely outweighs the benefit
- Periodic follow-up after cardiac transplantation	- Patient unable to cooperate or does not desire procedure

[a]See text for full details.

fraction of 10%, or multiple areas of ischemia is a class I indication for catheterization. These indications hold true even if the patient is asymptomatic. Positive stress tests without high-risk criteria are class II indications for LHC.

E. Ventricular arrhythmia. A history of sustained polymorphic ventricular tachycardia, without obvious metabolic cause, is considered a class I indication for LHC.

F. Left ventricular dysfunction. LHC can provide an estimate of left ventricular function and regional wall motion. Left ventricular dysfunction of unknown cause, with an ejection fraction of < 40%, is a class I indication for LHC to rule out CAD.

G. Valvular heart disease. LHC can be performed to assess the severity of outflow tract obstruction (aortic stenosis and hypertrophic obstructive cardiomyopathy). It can also help quantify aortic and mitral regurgitation (MR). With the advancements in Doppler and color echocardiography, the major role of cardiac catheterization is to provide confirmatory data and to rule out CAD as part of the operative workup. LHC has a class I indication in patients requiring valve surgery who are at risk for CAD. Most centers perform LHC before valve surgery in those older than 50 years to rule out clinically silent CAD. Younger patients may require LHC if cardiac risk factors are present or if coronary reimplantation may be needed as part of the surgery (homograft implantation, ascending aorta replacement, or Ross procedure).

H. Preoperative. LHC is performed before ascending aortic aneurysm surgery or some cases of ascending aortic dissection surgery. It is also performed on patients with congenital heart disease to evaluate lesions such as ventricular septal defects and to rule out concomitant coronary anomalies or atherosclerotic disease, if symptomatic. In patients with angina or a positive stress test who are to undergo high-risk surgery, LHC is given a class I indication.

III. CONTRAINDICATIONS.

The following are relative contraindications to LHC (see Table 64.1).

A. Coagulopathy. Coagulopathy must be corrected before elective catheterization. The usual recommendation for patients on warfarin (Coumadin) is to discontinue it 72 hours before the procedure. In elective cases, an international normalized ratio of < 1.8 is a cutoff that is often used. If the patient is heparinized, this is usually stopped 2 hours before the procedure. A platelet count of < 50,000 substantially increases the risk of bleeding. After thrombolytic therapy, bleeding is more likely and elective catheterization is best deferred. However, if the indication for the procedure is urgent, it is possible to proceed with caution, with blood products kept ready for support as needed. Antecedent glycoprotein IIb/IIIa inhibitor therapy poses much less of a risk. Body habitus is also a factor in deciding what level of anticoagulation is acceptable before a catheterization. Obesity increases the chances of bleeding (if multiple attempts at access are needed) and makes bleeding more difficult to detect. Finally, the availability of closure devices makes it possible to seal the artery after the procedure.

B. Renal failure. A rising creatinine is generally a reason to defer elective cardiac catheterization. In a patient on dialysis, catheterization is generally timed immediately after the dialysis. In a patient with stable but moderately severe renal failure, catheterization may be performed with an awareness of the increased risk of needing dialysis.

C. Dye allergy. A history of allergy to previous contrast administration should be sought. Although an allergy to shellfish and seafood has been linked to contrast reactions in some studies, other studies dispute such a relationship. Individuals with a history of asthma or atopy are at increased risk of developing contrast allergies. Treatment of patients with a history of dye allergy is described in Section **IV.F.2**.

D. Infection. Active infection is a reason to defer elective cardiac catheterization. Local skin infection at the site of the potential puncture is also undesirable. Fungal infection in groin creases should be controlled before elective cardiac catheterization by the femoral approach; this is a particular concern in obese patients. Alternatively, LHC may be performed through a brachial or radial approach in patients with fungal infection in groin creases.

E. **Laboratory abnormalities.** Severe anemia, hypokalemia, or hyperkalemia should be corrected before the elective procedure. In the presence of digitalis toxicity, elective catheterization is best deferred.

F. **Decompensated HF.** Severe HF raises the risks of cardiac catheterization. It is best to optimize medical therapy before elective catheterization. At a minimum, the patient should be able to lie supine without respiratory insufficiency.

G. **Severe peripheral vascular disease.** Symptoms of claudication warrant careful assessment of pulses. An inadequate lower extremity pulse favors an upper extremity approach. A synthetic vascular graft that is older than 6 months is not a strict contraindication to catheterization, but special care should be taken in gaining access as well as in obtaining hemostasis. However, the risk of embolization of friable atheroma or thrombus is heightened, and this risk increases with the age of the graft.

H. **Abdominal aortic aneurysm (AAA).** Presence of an AAA requires special care during a cardiac catheterization (see subsequent text). An arm approach obviates the need to cross the AAA altogether.

I. **Uncontrolled severe hypertension.** Blood pressure should be controlled before elective cardiac catheterization to maximize the safety of the procedure. In particular, severe bleeding can occur at the access site after sheath removal if the patient is very hypertensive, especially if above 180/100 mm Hg.

IV. PATIENT PREPARATION

A. **Informed consent.** A detailed discussion with the patient (and family) should outline the indication for the procedure, as well as the alternative treatment and diagnostic options. Specific mention of the serious risks of complications, such as death, MI, stroke, arrhythmia, bleeding, radiation exposure, and kidney failure, must be made (see complications in subsequent text). The possible need for emergency coronary artery bypass grafting (CABG) should be noted. The risk of serious complications should be individualized. Informed consent should be documented in the medical record.

B. **Precatheterization assessment.** Before proceeding with an LHC, a detailed clinical assessment is necessary, including a comprehensive history and physical examination. All peripheral pulses should be palpated, and arterial bruits, if any, should be documented before the catheterization as a baseline for future reference. In addition, laboratory data, including a comprehensive metabolic panel, complete blood count, and coagulation studies, should be obtained for all patients. Abnormalities in the laboratory parameters, if any, should be addressed before proceeding with LHC.

C. **Medications.** If percutaneous coronary intervention is likely, pretreatment with aspirin 325 mg by mouth (PO) should be given before the catheterization, as it has been shown to improve outcomes with angioplasty. If stenting is a strong possibility, clopidogrel 300 mg PO should be given as a loading dose before the procedure. Metformin should be stopped at the time of the procedure, although the risk of lactic acidosis is extremely low in a patient with normal creatinine.

D. **Education.** Patients should be warned that they might feel a hot sensation lasting about 30 seconds due to the injection of ionic contrast dye. Some patients may also feel nauseated. Patients should be specifically instructed to cough when they hear anyone in the room say "cough." This maneuver accelerates resolution of dye-induced bradycardia.

E. **Equipment.** Before performing a cardiac catheterization, it is essential to ensure that the monitoring equipment is fully functional. Continuous electrocardiographic monitoring of heart rate (HR), rhythm, and ST segments, an automated blood pressure cuff, and continuous pulse oximetry are mandatory. Resuscitation equipment should be tested and ready. In particular, defibrillators and intubation trays must be available next to the patient. If a long procedure is anticipated, many operators prefer placement of a Foley or Texas urinary catheter. Before actually beginning the procedure, the fluoroscopy and cine equipment should be tested by taking a picture

of the patient's nameplate. The usual frame rate of cine film is set at 30 frames/s; 60 frames/s can be useful for patients with tachycardia. In thin individuals who are bradycardic (< 60 beats/min), the frame rate can be lowered to 15 frames/s. In addition, the table should move freely to the level of the patient's groin.

F. Contrast dye

1. **Choice of contrast.** Ionic contrast dye was historically used during most cardiac catheterizations. In most circumstances, low-osmolar nonionic dye, which is now only slightly more expensive, can be used. The literature supports that nonionic dye produces less left ventricular dysfunction, bradycardia, and hypotension, as well as less nausea and emesis. Thus, it is useful in cases of suspected left main stenosis, severe left ventricular dysfunction, and severe aortic stenosis. Other indications for nonionic dye are severe renal dysfunction and a reported allergy to contrast dye. However, no reduction in acute renal failure or anaphylactoid reaction has been conclusively demonstrated with the use of nonionic dye. There is evidence that nonionic contrast is more thrombogenic than ionic contrast. Therefore, it should be used carefully in patients with acute coronary syndromes. Whenever nonionic contrast is used, 5 IU of heparin per cubic centimeter of contrast should be added.
2. **Dye allergy**
   a. **Premedication.** If a patient reports an allergy to contrast dye or a history of prior anaphylactoid reaction, it is customary to premedicate with steroids and antihistamines. Protocols vary widely. Common regimens include 50 mg of oral prednisone administered 13, 7, and 1 hour (q6h) prior to the procedure along with diphenhydramine 50 mg IV or orally 1 hour prior to the procedure. Intravenous steroids can be substituted in place of oral steroids 1 hour prior to the procedure (hydrocortisone 100 mg IV once). With a history of possible life-threatening dye allergies, it is also prudent to administer small quantities of dye (1 mL) and observe the patient for a few minutes before proceeding.
   b. **Treatment.** If a patient develops any sign of an allergic reaction, treatment should be prompt. If signs such as hives or rashes develop, treatment with diphenhydramine is usually sufficient. Hydrocortisone is also often given, though its effects may not manifest for several hours. In cases of oropharyngeal edema, bronchospasm, or hypotension, 0.3 mL of 1:1,000 epinephrine should be administered subcutaneously. With refractory symptoms, 10 μg/min of intravenous epinephrine can be administered until symptoms abate.
   c. **Latex allergy** has become increasingly recognized as a clinical entity, especially in patients who are health-care workers. True latex allergy can include urticaria, angioedema, laryngospasm, bronchospasm, and anaphylaxis. If a patient describes a possible latex allergy, allergy testing, including skin testing and rapid antigen serum testing, should be considered. Patients with latex allergy should be scheduled as the first case of the day to avoid latex dust from previous procedures. Written protocols outlining materials to be avoided should be strictly followed. A cart with latex-free items should be made available. The sheath is a source of latex exposure. Therefore, a sheathless approach involving catheter exchanges over a wire is preferred.
   d. **Sedation.** Commonly used sedatives include the benzodiazepines midazolam 1 to 2 mg IV or lorazepam 1 to 2 mg IV. Some operators use fentanyl 25 mg IV or morphine 1 to 2 mg IV for pain relief. Diphenhydramine 25 or 50 mg IV can also be used for sedation. Continuous pulse oximetry should be followed to ensure that sedation has not been excessive.
   e. **Radiation safety.** Radiation poses a threat to laboratory personnel; therefore, every effort should be made to reduce exposure. The source is scatter from the x-ray beam originating under the table. Lead aprons (with at least 0.5-mm thick lead lining) and thyroid collars are mandatory to minimize

radiation exposure. Leaded eyeglasses should also be considered. In addition, radiation badges are worn inside the lead apron and outside the thyroid collar to monitor cumulative radiation exposure. A leaded acrylic shield should be used between the patient and the operator closest to the patient. Standing further from the table also reduces radiation exposure by the inverse square of the distance. A number of additional steps can be taken to minimize radiation to both the operator and the patient. Fluoroscopy and, in particular, cine time should be minimized. The image intensifier should be positioned as close as possible to the patient to reduce radiation scatter. To decrease radiation, higher magnification should be used judiciously. "Coning down" on a region of interest with the use of collimators can also reduce the amount of radiation, as can the use of lung field collimators. Right anterior oblique (RAO) views produce less radiation scatter for the operator than left anterior oblique (LAO) views. Higher cine frame rates increase radiation exposure; use of 15 or 30 frames/s produces less radiation exposure than use of 60 frames/s. In the rare situation that a pregnant patient needs catheterization, a lead apron should be used. This precaution should also be taken for premenopausal women.

V. ACCESS SITE

A. Femoral artery. Femoral artery cannulation is the most common form of arterial access for cardiac catheterization (see Fig. 64.1). The patient is first positioned appropriately, with the knees about 12" apart. The table should allow enough movement to perform fluoroscopy of the groin. Anatomic landmarks are then identified. The inguinal ligament is located. Then the femoral pulse is palpated approximately 2 cm (finger breadths) below the inguinal ligament; this marks the site of arterial access.

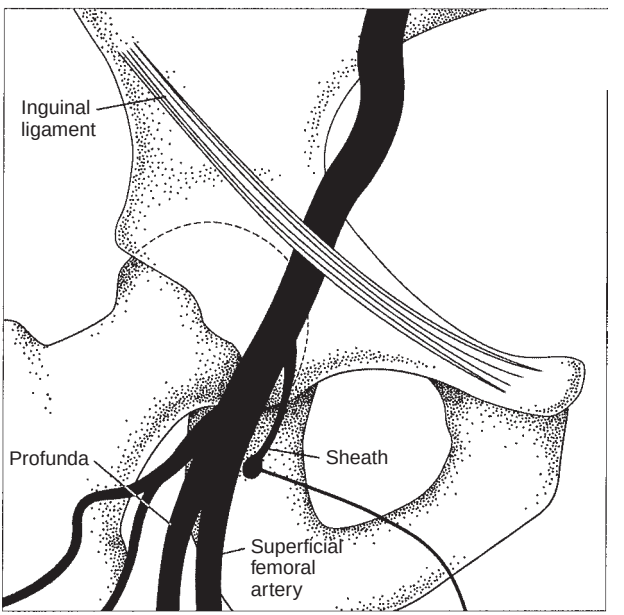

FIGURE 64.1 Landmarks for right femoral artery puncture.

Alternatively, fluoroscopy can be used to locate the femoral head. The entry point on the skin is located over the inferior border of the femoral head. Care must be taken not to enter the artery above the inguinal ligament, as this increases the chance of retroperitoneal bleeding. Arterial entry that is too low must also be avoided, as this can lead to pseudoaneurysm or arteriovenous fistula formation. Once the site of entry has been identified (and marked, if so desired), the area is cleaned with povidone iodine (Betadine) and surgically draped. Local anesthesia is given slowly (it hurts less when delivered slowly) while the clinician monitors the HR and watches for signs of a vagal reaction (nausea, lightheadedness, and yawning). The usual choice is procaine 1%. A subcutaneous wheal is raised with about 3 mL using a 25G needle. Next, an additional 6 to 10 mL is delivered to the deeper tissues with a 22G needle. In patients who are allergic to ester-type anesthetics, lidocaine 2% can be used. Once the site is anesthetized, an 18G Cook needle is inserted into the artery. Upon nearing the artery, a side-to-side motion of the needle indicates a position either medial or lateral to the artery. Up-and-down motion indicates correct positioning. In addition, when the needle is above the artery, it transmits the arterial pulsation to the fingertips. Once brisk arterial blood return is established, a 0.035″ J-tipped 45-cm guidewire is inserted, the needle is withdrawn, and an arterial sheath with a dilator is placed over the wire. Then the wire and dilator are removed. The sheath is then flushed with saline. A 5F or 6F sheath is generally used for diagnostic catheterizations in the United States, though 4F sheaths are often used in Europe. An 8F sheath is used for acute cases or planned interventions. A 5F sheath is preferred over larger sheaths for patients with peripheral vascular disease.

B. Brachial and radial approach. In certain patients, it may be desirable to perform the catheterization by a brachial or radial route, for which specialized equipment is available. Percutaneous brachial or radial access is similar to the femoral approach described above. In addition, a surgical cut-down was historically performed to enter the brachial arteries under direct visualization, though surgical cut-downs are rarely performed in the modern era. For a left brachial approach, Judkins catheters are adequate. For a right brachial approach, Amplatz or multipurpose catheters are used, although it may be difficult to engage a left internal mammary artery (LIMA) graft from the right arm; a specially designed brachial internal mammary artery catheter is available for the latter purpose. In rare circumstances, an axillary approach can be used, though the rate of neurovascular complications is higher.

Increasingly, operators now use the **radial approach** as the default approach. The radial approach has been associated with fewer bleeding complications when compared with the femoral approach and does not require a long period of immobilization of the patient afterward. It is thus preferred by patients. Radiation exposure data have been conflicting and can be influenced by multiple factors including the familiarity of the operator with the radial approach. To obtain vascular access from the radial site, the Allen test should be performed prior to radial artery catheterization. The patient's arm is abducted at a 70° angle and the wrist is hyperextended. The site is prepped and draped in a manner similar to the femoral and brachial access sites. Local anesthetic is injected. The radial site should be roughly 1 cm above the styloid process. Either an 18G needle or a micropuncture needle (22G) is inserted at 30° to 45° into the radial artery. A sheath is advanced in the same manner as described above using the Seldinger technique. Local infusions of nitroglycerin and/or verapamil can be injected to decrease radial artery spasm. Heparin 3,000 to 5,000 IU should be considered to avoid sheath thrombosis. Once access is obtained, a similar process of advancing a catheter over a guidewire is performed as in other access sites. Diagnostic and interventional procedures can be performed via the radial artery using traditional catheters as well as a number of newer catheters designed specifically for radial access such as the Jacky catheter or the Tiger catheter.

C. Special situations. In patients with prosthetic femoral grafts, it is preferable to use a dilator first before placing the sheath to prevent the sheath from kinking as it passes through the graft. This technique is also useful in obese patients. If a synthetic graft is old, fluoroscopy can be performed to determine if the graft is heavily calcified—a sign that it may not seal well after sheath removal. In patients with tortuous or diseased vessels, a Wholey wire or Terumo glidewire can be used to get catheters up the aorta. If marked iliac tortuosity is present and causes inability to torque catheters, a long sheath can be used to straighten out the iliac vessel. At times, a stiffer wire (such as an Amplatz wire) can provide better support to advance catheters. In patients with an AAA for whom a femoral approach is chosen, exchange wires should be used for every change of catheter. Use of a softer wire (such as a Wholey wire) can prove less traumatic to the vessel, as can use of a JR 4 to direct the guidewire.

D. Catheters. The catheters commonly used for coronary angiography include the Judkins and the Amplatz systems. For the left coronary artery (LCA), the size of the Judkins left (JL) catheters ranges from JL 3.5 to JL 6. The Amplatz left (AL) catheters used commonly range in size from AL I to AL III (Fig. 64.2 shows the shapes of the JL and AL catheters). Similarly for the right coronary artery (RCA), the Judkins right (JR) catheters range in size from JR 3.5 to JR 6. The Amplatz right (AR) catheters commonly used range from AR I to AR III. In addition, there is also an AR-modified catheter (Fig. 64.3 shows the shapes of the JR and AR coronary catheters commonly used). Other catheters used include the multipurpose catheters (multipurpose A1, A2, B1, and B2 catheters), which can be used for cannulating the left and right coronary arteries and bypass grafts. For coronary bypass grafts, the right or the left coronary bypass catheters may be used. The internal mammary artery may be cannulated using either the internal mammary or the internal mammary special catheters (see Fig. 64.4).

VI. TECHNIQUE

A. Engaging the vessel

1. **Left coronary artery.** Catheters are flushed with heparinized saline and passed through the sheath over a J-tipped guidewire. Using fluoroscopic guidance in the LAO projection, the left main coronary artery is cannulated, typically with a JL 4 (see Fig. 64.2). The catheter tip should be coaxial to the left main coronary artery, meaning that its tip should not be touching the upper wall of the left main coronary artery. In a small person, a JL 3.5 (see Fig. 64.2) catheter can be used. In a larger person or a person with a dilated aorta, a JL 5 or even a JL 6 (see Fig. 64.2) can be used. If the catheter does not engage the left main ostium easily, a slight clockwise or, more often, a counterclockwise rotation of the catheter hub may help. With the JL catheters, unless the aorta is dilated and provides no hinge point for the JL catheter, counterclockwise rotation moves the catheter tip anteriorly and clockwise rotation moves it posteriorly.

   Care should be taken to prevent the catheter from too deeply engaging ("deep-seating") the left main coronary artery. The pressure waveform must be observed for **damping** (a decrease in the systolic pressure) or **ventricularization** (when the waveform looks like a ventricular pressure tracing), both of which indicate a need to pull the catheter back and also raise the possibility of significant left main CAD. An adequate amount of dye reflux should be seen, unless ostial disease is present. If significant left main CAD is suspected, a cusp view (with the catheter placed in the left sinus of Valsalva) can be taken. Injection of contrast should be gentle and pressure gradually increased ("ramping"). Enough contrast should be injected to opacify the entire coronary artery and ensure reflux into the aorta (usually about 8 mL for the LCA). Injection force should be forceful enough to prevent "streaming," the inadequate opacification of coronary arteries that can create the illusion of stenoses. Care should be taken to inspect the injection syringe for air bubbles before each injection and to hold the syringe upright while injecting.
2. **Right coronary artery.** Catheterization of the RCA is similar to that of the LCA, except that a JR 4 (see Fig. 64.3) is advanced into the right coronary cusp, again in the LAO projection. The RCA is usually located anteriorly in the right sinus, in a position that is lower than the LCA ostium. As the catheter is slowly pulled back 2 cm above the aortic valve, it is rotated clockwise, causing it to engage. With the JR catheter, clockwise rotation moves the catheter tip anteriorly. In addition, clockwise rotation can cause the catheter tip to dip downward. Thus, it may be necessary to apply backward traction on the catheter as it is being rotated clockwise. Sometimes, it is necessary to repeat the clockwise rotation at different levels in order to engage the right coronary ostium. If the JR 4 does not easily engage the RCA or if the pressure dampens, ostial disease, spasm, selective intubation of the conus (which arises separately 50% of the time), or anatomic variation in the direction of the proximal RCA should be suspected. A cusp view can be taken to clarify these situations. Care should be taken to avoid subselectively intubating the conus branch.

   If difficulty is encountered in engaging the RCA because of the orientation of the ostium, a 3DR or a no-torque right catheter can be useful (see Fig. 64.3). Both catheters are designed to be placed above the aortic valve and pulled back without torquing maneuvers. An Amplatz or multipurpose catheter (see Figs. 64.3 and 64.4) can be useful for an upwardly angled ostium. An anterior or posterior origin can often be engaged with an Amplatz catheter. The most common cause of an incomplete LHC is a high and anterior RCA. To locate its ostium, less clockwise torque should be applied to the catheter so that it faces more anteriorly. Then the catheter can search for the ostium superior to the usual location. Less dye is needed to opacify the RCA than the LCA; overinjection can cause ventricular fibrillation. Sometimes, if a catheter is tenuously engaged, particularly in the right coronary ostium, a deep breath can dislodge it and should be avoided.

3. **Left internal mammary artery.** Catheterization of the LIMA is done either in the posteroanterior or shallow LAO projection. First, the catheter (usually a JR 4 catheter or a LIMA catheter; see Figs. 64.3 and 64.4) is positioned by pulling it back in the aorta while applying counterclockwise torque until it enters the left subclavian artery. At this point many operators will obtain an angiogram of the left subclavian artery to rule out a stenosis proximal to the LIMA and to give a hint of the angle of takeoff of the LIMA. The wire (J-tipped guidewire or Wholey wire) is then advanced into the subclavian artery. Next, the catheter is advanced over the wire into the subclavian artery, the wire is removed, and the catheter is slowly pulled back with a slight counterclockwise rotation until it engages the ostium of the LIMA. Movements around the ostium must be gentle to reduce the risk of dissection of the vessel; frequent test injections are helpful. In addition, if a 6F sheath is in place, switching to a 5F catheter will likely result in less trauma to the ostium of the LIMA. Turning the head to the left or right and pulling the arm caudally are maneuvers that can help engage the LIMA. If the ostium points downward at a sharp angle, the LIMA catheter is more likely to engage it selectively. The special LIMA catheter provides a slightly different angulation. It is best to use nonionic contrast to minimize the pain caused by ionic dye running through the arteries of the chest wall. If the ostium cannot be engaged successfully, a nonselective angiogram can be taken with the tip of the catheter as close to the ostium as possible. A blood pressure cuff should be inflated above systolic pressure in the left arm to facilitate dye movement down the LIMA.
4. **Right internal mammary artery (RIMA).** Catheterization of the RIMA is similar to that of the LIMA. The catheter (either JR 4 or LIMA; see Figs. 64.3 and 64.4) is placed in the brachiocephalic trunk by pulling it back in the aorta while applying counterclockwise rotation. The wire is advanced into the right subclavian artery. Care must be taken to avoid the right carotid artery. The wire is removed and the catheter is pulled back until it engages the ostium of the RIMA.
5. **Saphenous vein grafts (SVGs).** Catheterization of SVGs depends on the specific type of graft. The grafts are by necessity anastomosed to the anterior surface of the aorta. The orientation of SVGs from caudal to cranial is usually as follows: RCA, left anterior descending artery (LAD), diagonal branches of LAD, and marginal branches of left circumflex coronary artery (LCX). In the LAO view, grafts to the RCA usually point to the patient's right, whereas grafts to the left system are usually oriented more to the patient's left. It is the practice of some surgeons to place circular graft markers around the ostia of the vein grafts on the outer surface of the aorta. In the steep LAO projection, the catheter tip should extend beyond the plane of these markers, if the catheter is truly engaged in a vein graft. Injections into presumed vein graft stumps should be forceful to ensure that the graft is truly occluded, as opposed to poor opacification from a tenuously engaged catheter. Review of the operative note is mandatory before catheterization to know where grafts were placed. In particular, it should be noted whether any LIMA or RIMA grafts are in situ or free (attached to the aorta). A previous catheterization, if done, should be reviewed. Particular attention should be paid to the location of the grafts. The relative relationship with surgical clips should be noted, as this will save time and effort in finding grafts during the catheterization. If a graft cannot be found or a stump identified during a catheterization, an aortogram should be performed (Section **VI.E**).
   a. **SVG to RCA.** Engaging this graft can be as simple as pulling back on the JR 4 as it sits in the ostium of the RCA while in the LAO projection. Often, this graft has a steep downward orientation from the aorta. In this situation, a multipurpose catheter can be useful in engaging the graft. The multipurpose catheter can enter deeply into the graft if not handled carefully. Alternatively, a right bypass catheter or a right-modified Amplatz catheter can be useful in engaging the RCA graft.

b. **SVG to LAD.** The graft to the LAD is most easily engaged in the RAO view. To engage this graft, it is necessary to withdraw the catheter from the SVG to the RCA by pulling back. If the catheter does not fall into place, clockwise rotation of the JR 4 at an area cranial to the SVG to RCA graft ostium will locate the LAD graft. It may be necessary to move the catheter up and down along the anterior surface of the aorta several times. Left bypass, left Amplatz, and multipurpose catheters are all alternative catheters that can be used. A similar clockwise rotation to move the catheter tip along the anterior aortic surface is necessary.

c. **SVG to LCX.** To engage this graft, it is necessary to withdraw the catheter from the SVG to the LAD by pulling back, while remaining in the RAO projection. If the catheter does not fall into place, clockwise rotation of the JR 4 at an area cranial to the SVG to LAD graft ostium will locate the LCX graft. The technique is otherwise similar to that for engaging the graft to the LAD.

B. Imaging the vessels

1. **Normal coronary anatomy.** The left main coronary artery originates from the left coronary cusp. It usually bifurcates into an LAD and an LCX, although it sometimes trifurcates to include a ramus intermedius. The LAD courses along the anterior interventricular groove, supplying numerous septal perforators to the septum and a variable number of diagonal branches to the anterolateral wall of the left ventricle, and usually continues to the apex. The LCX courses along the left atrioventricular (AV) groove, providing a variable number of marginal branches to supply the lateral wall. In some institutions, the first marginal branch is called the high lateral branch of the circumflex, with subsequent branches called lateral or posterolateral branches depending on their destination. The LCX continues in the AV groove for a variable distance. In patients in whom the LCX is dominant (see subsequent text), the LCX reaches the posterior interventricular groove and gives rise to a posterior descending artery (PDA) branch.

   The RCA originates from the right coronary cusp and courses along the right AV groove, providing atrial branches (to the right atrium) and marginal branches (to the right ventricle). A conus branch originates as the first branch from the proximal RCA to supply the right ventricular outflow tract; about half of the time, this branch has an ostium that is separate from the RCA ostium. It is usually unnecessary to visualize a separate conus branch, unless collaterals to the LAD are suspected. The RCA gives off a branch to the sinus node about 60% of the time (otherwise a left atrial branch of the LCX serves this function). The first major branch the distal RCA gives off is the PDA, in a right dominant system. **Dominance** refers to which artery gives off a PDA and supplies the posterior part of the heart. In about 85% of patients, this will be the RCA; in 7% the RCA and LCX will be codominant; and in another 8% the LCX will be dominant. The PDA courses along the inferior interventricular groove, providing septal perforators to supply the inferior septum. After giving off a PDA, the RCA continues as a posterolateral segment supplying a variable number of posterior ventricular branches. From this posterolateral segment, the RCA usually (90% of the time) provides a branch to supply the AV node.

2. **Basic principles.** Several views of the coronary arteries are required to prevent excessive overlap of vessel segments and to delineate the severity of stenoses. A general principle that is useful is that in an RAO view the spine is on the left of the screen, conversely, in an LAO view the spine is on the right of the screen. Cranial views bring the silhouette of the diaphragm into the field of view. The diagonal and obtuse marginal branches tend to move in synchrony, because they supply the lateral aspect of the heart, whereas the LAD is located on the anterior portion of the heart. The AV continuation of the LCX lies in the AV groove, and (in patients with sinus rhythm) it has an "atrial kick" to it. This type of atrial kick can also be seen in atrial branches from either the LCX or the RCA. In the RAO view, a diagonal branch, and not the LAD itself, usually lies on the heart border. In the LAO view, the LAD runs along the border of the heart silhouette, not the

diagonal branches. Caudal angulation tends to move posterior vessels (such as the posterolateral branches of the RCA or the obtuse marginal branches of the LCX) inferiorly. Cranial angulation tends to move posterior vessels superiorly.

Patients should be instructed to take in a deep breath and hold it before most views for the purpose of moving the diaphragm out of the way. The RAO cranial view can be done at end of expiration to facilitate the splaying out of the diagonals from the LAD or at end of inspiration to view the proximal LCX. The LAO caudal can be done at end of expiration to visualize the left main and ostial LAD or at end of inspiration to view the LCX. Panning motion should be smooth and slow. It is best to wait for two to three systolic cycles and focus on proximal vessels before panning down the length of the artery of interest. It is important to pan to look for collaterals.

3. **Different views** (see Figs. 64.5 to 64.11)
   a. **Left coronary artery.** There is wide variation in the sequence of views obtained. Many operators start with a posteroanterior view and focus on the left main coronary artery, sometimes with a coned-down view to improve resolution. The problem with a pure posteroanterior view is that there is significant overlap with the spine. Therefore, a little bit of RAO angulation ("shallow RAO") can be used to get the coronaries off the spine. A steeper amount of RAO provides greater separation of the LAD from the LCX. A slight amount of caudal angulation can be used to decrease the foreshortening of the proximal circumflex in the straight RAO view and to place the diagonals below the LAD. Therefore, a **20° RAO, 20° caudal** is often the first view, displaying the entire left coronary system. This view also provides

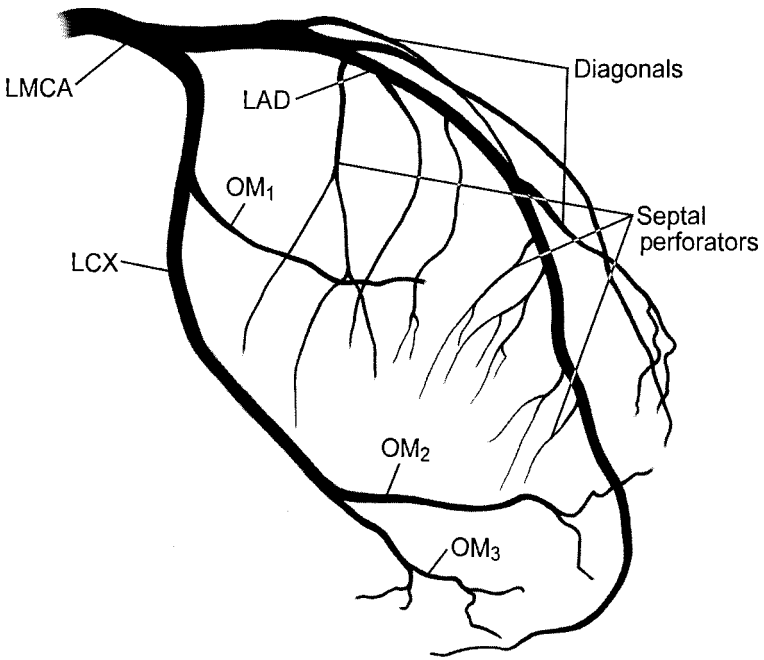

FIGURE 64.5 Posteroanterior view of left coronary artery. LMCA, left main coronary artery; LCX, left circumflex coronary artery; LAD, left anterior descending artery; OM_1, obtuse marginal branch 1; OM_2, obtuse marginal branch 2; OM_3, obtuse marginal branch 3.

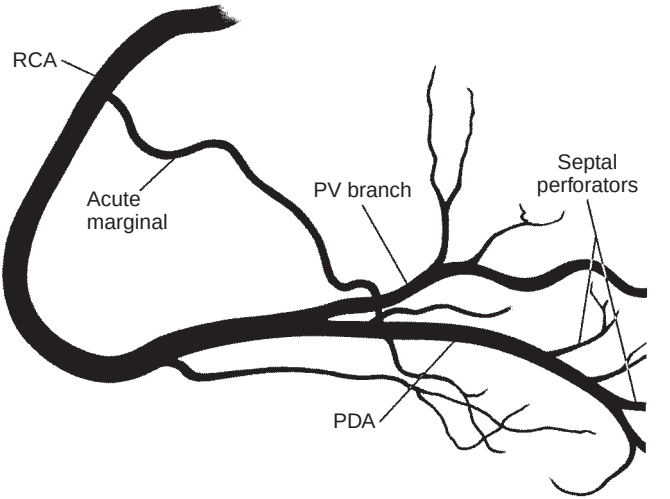

FIGURE 64.10 Left anterior oblique view of right coronary artery. RCA, right coronary artery; PV branch, posteroventricular branch; PDA, posterior descending artery.

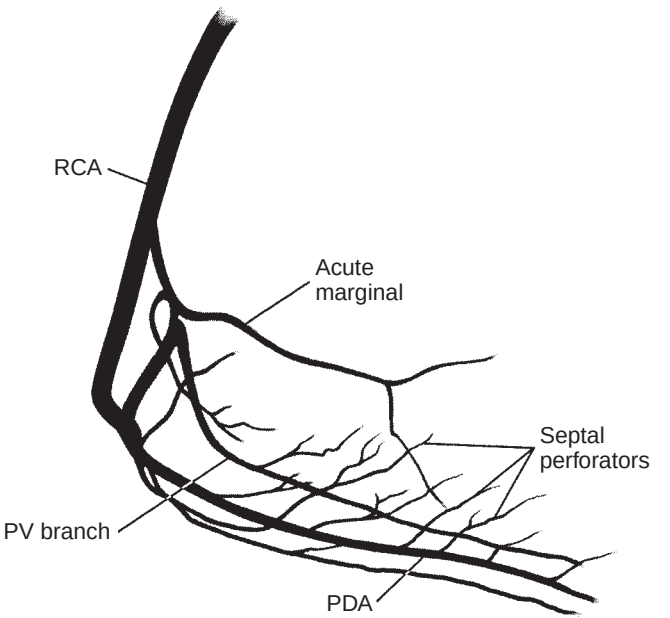

FIGURE 64.11 Right anterior oblique view of right coronary artery. RCA, right coronary artery; PV branch, posteroventricular branch; PDA, posterior descending artery.

a good view of the proximal LCX and of the origin of a ramus intermedius branch, if present. The contour collimator (called the wedge or the shield) should be moved to the upper right of the screen. A **30° RAO, 25° cranial** view can be used to separate the diagonals from the LAD, placing them above the LAD. The wedge should be placed in the upper right of the screen. A posterior–anterior view (PA) with **40° cranial** angulation can be useful in viewing the mid and distal portions of the LAD. The **45° LAO, 30° cranial** view is good for separating the LAD from its diagonal branches, especially for vertically oriented hearts. There should be enough LAO angulation to get the LAD off the spine. This view can also be good for a left-sided PDA branch. Steeper degrees of LAO further separate the LAD from the LCX and can get the LCX off the spine, but they can also cause the origins of the diagonals to overlap the LAD and cause the distal LAD to overlap the diaphragm. The **45° LAO, 30° caudal** ("spider" view) is useful for looking at the left main coronary artery and the proximal origin of the LCX. The proximal LAD is also seen but is foreshortened, unless the heart is horizontal in orientation. There must be enough LAO to get the cardiac silhouette off the spine. There is usually no need for a wedge, as it further increases the haziness of this view. Minimal to no panning is required. The **lateral** view provides delineation of the mid-LAD. In addition, the distal LAD does not overlap the diaphragm and the LCX is off the spine. The patient's hands should be placed behind the head for the lateral view. The shield should be placed above the course of the LAD. Panning involves dropping the table height and moving the table cranially. The **PA with 30° caudal** angulation provides a good view of the LCX.

b. **Right coronary artery.** The RCA is usually viewed in LAO and RAO views. The **30° RAO** view provides a good view of the proximal and mid-RCA and also of the PDA, which is laid out lengthwise. Cranial angulation can help separate the PDA from the distal vessel. The **40° LAO** view provides a good view of the proximal and mid-RCA, and if cranial angulation is added, a good view of the posterolateral arteries. The **PA with 30° cranial** can provide a useful view of the origins of the PDA and posterolateral branches. The lateral view of the RCA can provide a good view of the mid-RCA. In the RAO view, the right atrium and ventricle are separated by the RCA in the AV groove. Thus, atrial branches will be directed toward the atrium and marginal branches will be directed toward the ventricle.

c. **Bypass grafts.** An LAO view and an RAO view are required to visualize the body of the graft. Additional views are dictated by the grafted vessel. A particularly useful view for the LIMA–LAD anastomosis is the lateral view; cranial LAO and cranial RAO views can also be useful. The graft to the diagonal can be visualized in the cranial LAO and cranial RAO views. The graft to the marginal branch can be seen in the RAO and lateral views. The graft to the distal RCA can be visualized in the cranial LAO and lateral views.

4. **Congenital coronary artery anomalies.** Coronary artery anomalies should be suspected if there is an absent coronary artery and a large area of myocardium that appears nonperfused. The most common anomaly is an absent left main coronary artery trunk, in which the LAD and LCX have separate ostia (incidence 0.47%). If the LAD is first cannulated, the LCX can be engaged with a clockwise rotation; sometimes one size larger catheter (JL 5) is needed. Likewise, if the LCX is first cannulated, counterclockwise rotation, perhaps with a smaller-sized catheter (JL 3.5), is needed to engage the LAD. Other common anomalies in order of importance are the LCX originating from the right sinus of Valsalva (0.45%) and the RCA originating from the ascending aorta above the sinus of Valsalva (0.18%). The RCA originating from the left sinus of Valsalva is the next most common anomaly, originating superior and anterior to the left main (0.13%).

The origin of the left main artery from the right sinus is even less common (0.02%), but it can result in sudden death if the left main artery passes between the aorta and the pulmonary artery (extremely rare). The left main artery can also pass into the ventricular septum (most common), anterior to the pulmonary artery or posterior to the aorta. The 30° RAO view can help define the relationship between the coronary artery and the great vessels. If the course is septal, septal perforators can be seen originating from the left main.

The other coronary anomalies occur much less frequently. The Amplatz (left or right, depending on the cusp of origin) and multipurpose catheters are especially useful in cannulating anomalous coronary arteries.

Although not truly a congenital anomaly, every angiographer should be aware of **myocardial bridging**. This is an apparent narrowing of a coronary artery (usually the mid-LAD) that is present only during systole. There have been reports of bridging involving the diagonal branches of the LAD, the marginal branches of the LCX, and the distal RCA. Because the majority of coronary blood flow occurs during diastole, myocardial bridges are rarely pathologic, but there have been patients treated with CABG and, more recently, stenting. Nitroglycerin, by dilating epicardial vessels, can make bridging seem even more pronounced. A phenomenon similar to bridging can occur in hypertrophic obstructive cardiomyopathy, in which septal perforators from the LAD can become obliterated during systole.

5. **Quantification of coronary stenosis.** It is important to always obtain at least two perpendicular views of each coronary artery lesion. A single view, or even multiple views, can miss an eccentric lesion. Severity of a lesion is based on percent diameter stenosis compared with a "normal" reference segment. Lesions are generally classified as severe if 70% or more are in the LAD, LCX, and RCA or 50% are in the left main artery. When measuring the size of vessels and stenoses, it is useful to note that a 6F catheter has an external diameter of 2 mm. Formal quantitative coronary angiography or use of calipers can improve the measurement of coronary artery stenoses. Quantitative coronary angiography decreases the interobserver and intraobserver variabilities of grading stenosis severity. The minimal luminal diameter in the most severe view correlates best with perfusion imaging; minimal luminal diameters < 1.2 to 1.5 mm in proximal vessels typically reduce hyperemic flow.
6. **Limitations of coronary angiography.** Sometimes the severity of a lesion is difficult to gauge based on visual angiographic estimates alone, particularly in the presence of diffuse disease. Angiography only provides an outline of the lumen, the so-called luminogram. In addition, the angiogram can underestimate the presence of atheroma because of outward remodeling of the arterial wall (the Glagov phenomenon). Furthermore, angiography can only visualize arteries > 200 μm in diameter. The physiologic importance of 40% to 70% stenoses cannot be determined by angiography alone, and flow limitation should be demonstrated before percutaneous intervention. Techniques such as intravascular ultrasound and determining the fractional flow reserve can aid in determining whether ambiguous lesions on angiography are significant. Intravascular ultrasound provides a 360° tomographic view of the vessel lumen rather than a two-dimensional luminogram. Diagnostic applications of **intravascular ultrasound** include **imaging of angiographically indeterminate lesions, assessment of left main CAD, detection of transplant coronary vasculopathy, and identification of vulnerable plaques**. Intravascular ultrasound and optical coherence tomography can also be used during coronary interventions to help guide angioplasty, atherectomy, and stent placement (see Chapter 65, Percutaneous Coronary Intervention, for more details on these adjunct techniques of imaging).

C. Crossing the aortic valve

1. **Normal aortic valve.** The pigtail catheter is most commonly used to cross native aortic valves. Tissue valves can also be crossed, but crossing mechanical valves (e.g., St. Jude, Björk-Shiley, and Medtronic-Hall) risks catheter entrapment and is best

avoided. The catheter should be made to loop above the aortic valve. When pulled back very slowly, the catheter should give in, and it can then be rapidly advanced into the left ventricle during systole. Having the patient take a deep breath and hold it while the pigtail catheter is being unlooped can facilitate the passage of the catheter into the left ventricle. Sometimes the guidewire itself may be useful in crossing the valve, in which case the catheter is simply advanced over the guidewire into the left ventricle. A single operator can cross the aortic valve without assistance, but if two operators are present, one can move the catheter and change its orientation while the other moves the wire back and forth. The pressure in the left ventricle is recorded continuously; the catheter is pulled back into the aorta in a single motion to determine the aortic pressure, and the pullback pressure gradient can be calculated.

2. **Aortic stenosis.** In more severe cases of aortic stenosis, difficulty may be encountered in passing any catheter across the aortic valve. In this circumstance, a 0.038″ straight-tipped wire can be used to cross the valve. If this method is elected, some operators recommend a 5,000 IU bolus of heparin. The timer should be started, and not more than 3 to 4 minutes should be allowed per attempt at crossing. Between each attempt the wire should be withdrawn and wiped, blood aspirated and discarded, and the catheter flushed. Special care must be taken during this maneuver to avoid perforating the aortic cusps or potentially dissecting the coronary ostia. If a 6F sheath is used, a 5F pigtail catheter often provides the correct angle for wire passage; in addition, aortic and femoral pressures can be recorded concurrently and compared with the left ventricular pressure simultaneously using two transducers. A JR 4 or AL I catheter can also provide the correct orientation for wire passage across the aortic valve. The combination of a Feldman catheter and a Rosen wire is an alternative approach to cross stenotic aortic valves. Another way to determine the pressure gradient is to use a double-lumen pigtail catheter and measure the left ventricular and aortic pressures simultaneously.

D. Left ventriculography

1. **Setting up the view.** The pigtail catheter (commonly the angled version) is positioned in the midcavity of the left ventricle. The pigtail catheter should look like a "6" in the RAO projection. If the pigtail catheter twists with each beat, this indicates that it is caught in the mitral valve apparatus and needs to be repositioned. The monitor should be observed for ectopy. Once a stable rhythm is present, ventriculography can proceed. First, the left ventricular end-diastolic pressure (LVEDP) should be measured on a 40 scale. In patients with an elevated LVEDP (> 25 mm Hg), a left ventriculogram is generally contraindicated. If the decision to proceed with the left ventriculogram is made, sublingual nitroglycerin should first be given to lower the LVEDP. With more moderate degrees of left ventricular dysfunction, nonionic dye, which is less of a myocardial depressant, can be used. Digital subtraction can be used instead of cinefluoroscopy to obtain the left ventriculogram. This allows a smaller amount of contrast to be used. With digital subtraction, the view must be carefully centered because panning is not possible. **The left ventriculogram is best avoided in patients with critical aortic stenosis, significant left main artery disease, or severe left ventricular dysfunction**.
2. **Views.** The **30° RAO** view is used to look at the overall left ventricular function. In particular, the anterior, apical, and inferior walls can be assessed (see Fig. 64.12). Some operators routinely pan to the LIMA to assess its patency in a patient who might require CABG. The RAO view is also useful to assess mitral leaflet prolapse and MR. The LAO cranial view can also be used to assess MR, and it avoids the overlap of the aorta with the left atrium that occurs in the RAO view. **MR** can be graded on a scale of 1 to 4; 1 represents trace MR, with mild left atrial opacification that clears with one beat; 2 represents a mild to moderate degree of opacification, though less than that of the left ventricle; 3 represents moderate to severe opacification of the left atrium equal to that of the left

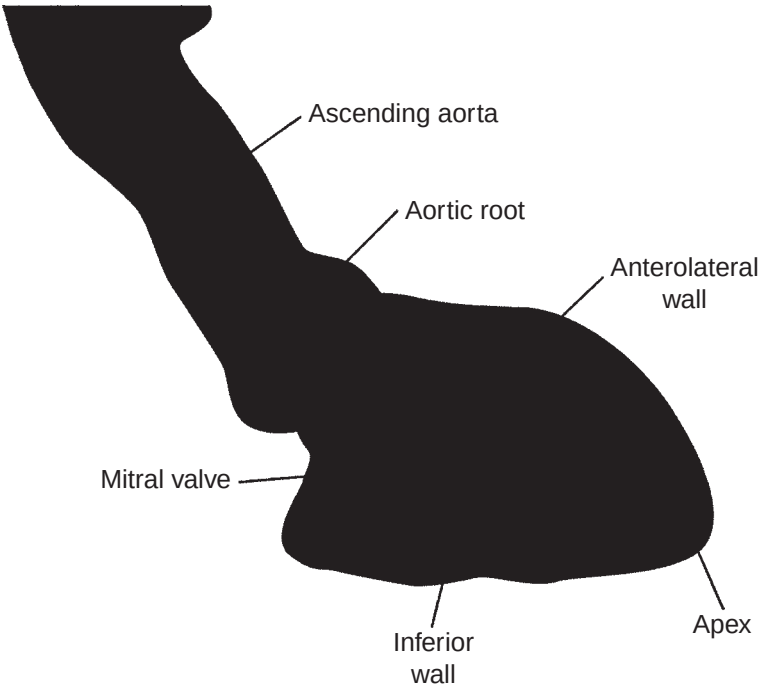

FIGURE 64.12 Thirty-degree right anterior oblique view of the left ventricle.

ventricle; and 4 represents complete opacification of the left atrium greater than that of the left ventricle. Panning toward the left atrium may be needed if MR is present. The catheter itself can cause MR if it is caught in the mitral valve apparatus or if it induces premature ventricular contractions. The correlation between angiographic and echocardiographic MR is excellent. The **60° LAO** projection allows evaluation of the septum and the posterior and lateral walls (see Fig. 64.13). Ventricular septal defects are best identified in the LAO projection with slight cranial angulation. If biplane imaging capability exists, RAO and LAO views of the left ventricle can be obtained simultaneously.

3. **Settings.** For a ventriculogram, the flow injector can be set at a rate of 10 to 15 mL/s for a total volume of about 35 to 50 mL, with a rate rise of 0.4 second (to minimize ectopy and to keep the catheter from moving abruptly) and a pressure of 600 PSI. The exact settings will vary depending on the size of the heart and the need to limit contrast.

E. Aortography. Aortography is usually performed in the LAO position, with the catheter about 2 cm above the aortic leaflets. Compared with a ventriculogram, a larger volume of contrast is needed to opacify the aorta. The flow injector is set to a higher total volume than for the left ventriculogram, usually about 60 mL at a rate of 20 to 25 mL/s. No rate rise is necessary (other than to keep smaller catheters from moving), and a pressure limit of 600 PSI is used. **Aortic insufficiency** can be identified with a grading system similar to that of MR; 1 represents trace aortic insufficiency that clears from the left ventricle with each beat; 2 represents mild left ventricular opacification that takes more than one beat to clear; 3 represents moderate left ventricular opacification

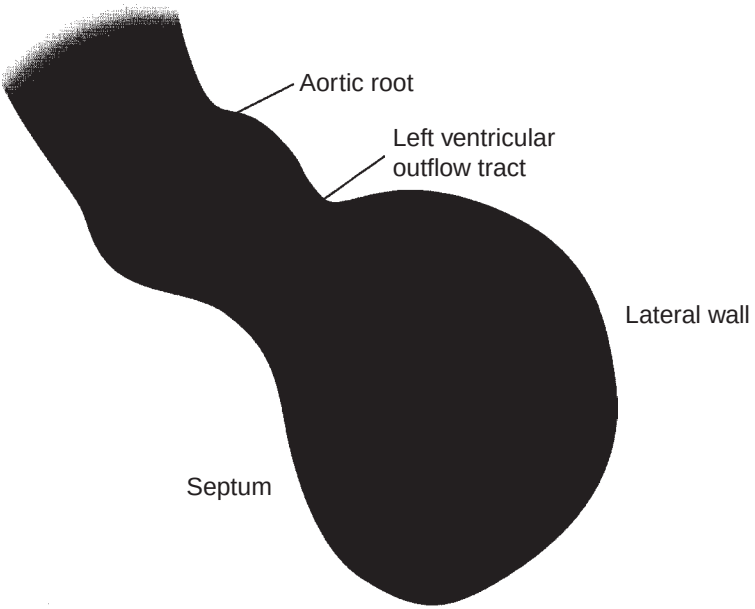

FIGURE 64.13 Sixty-degree left anterior oblique view of the left ventricle.

equal to that of the aortic root; and 4 represents complete opacification of the left ventricle greater than that of the aortic root. Diseases of the aorta such as aneurysms or dissection can also be identified. An aortogram can also aid in nonselective visualization of anomalous coronary arteries or grafts that are difficult to engage. However, the absence of filling of a bypass graft on an aortogram does not exclude its presence. The aorta must be completely opacified to ensure that grafts are seen.

An aortogram can be performed with the pigtail catheter placed in the descending aorta slightly above the level of the origins of the renal arteries (the L1 vertebral body) to rule out **renal artery stenosis**. A JR 4 can be used to obtain selective renal arteriograms by turning the tip of the catheter so that it points to either the left or the right in the posteroanterior view. The catheter is then gradually pulled back when it is in the vicinity of the renal artery ostia until it engages. Digital acquisition should be used.

Carotid angiography is sometimes necessary to confirm the degree of carotid artery stenosis seen on a noninvasive study. A variety of catheters (the Headhunter and Newton series) can be used to selectively cannulate the common carotid artery. These catheters are advanced to the aortic arch over a guidewire and pulled back to engage the artery of interest. A Newton 5 can be used to engage the right common carotid artery and a Newton 2, with its smaller curve, can be used to engage the left common carotid artery. There is a 0.5% to 1% risk of stroke with this procedure. Digital acquisition and use of nonionic contrast are mandatory.

F. **Pharmacologic testing.** In patients in whom coronary artery spasm is suspected, intravenous methylergonovine can be given to provoke spasm. Once significant angiographic stenosis has been ruled out, 0.05 mg of intravenous methylergonovine is administered. If the patient develops his or her typical chest pain or ST elevation on electrocardiographic monitoring, the coronary arteries are catheterized immediately. The electrocardiographic changes can help determine which coronary artery to cannulate

first. If there are no electrocardiographic changes or chest pain, the right coronary artery (which is statistically more likely to have spasm) and then the left coronary artery should be recatheterized 5 minutes after the methylergonovine has been administered. A positive response consists of a focal area of spasm that is relieved by intracoronary nitroglycerin (a usual dose of 100 to 200 μg). Diffuse spasm can be physiologic, and it is also managed with nitroglycerin and verapamil (also 100 to 200 μg). Because the half-life of methylergonovine is longer than that of sublingual nitroglycerin, it is important to realize that spasm can recur after a dose of nitroglycerin. If the initial dose of methylergonovine does not provoke a response, an additional dose of 0.2 mg can be given a few minutes after the first. Alternatively, some operators prefer giving a single dose of 0.2 mg.

Intracoronary vasodilators such as nitroglycerin are often used in the assessment of coronary anatomy. For example, if the operator is unsure if what appears to be ostial disease of a coronary artery may in fact be catheter-induced ostial spasm, an intracoronary injection of nitroglycerin and repeat angiography can help clarify. For more on the use of intracoronary vasodilator therapy (including nitroglycerin, nitroprusside, and adenosine) in the assessment and treatment of CAD, please see Chapter 65, Percutaneous Coronary Intervention.

Intravenous infusion of dobutamine can be useful in the evaluation of patients with low-flow/low-gradient aortic stenosis and left ventricular dysfunction. These patients can be a challenging population to evaluate, as it is unclear if the valve stenosis is in fact severe or moderate. The measurement of peak valve gradients and valve area at baseline and during administration of a dobutamine infusion can help clarify this question. Patients who do not have true anatomically severe aortic stenosis will exhibit an increase in valve area, with little change in the peak gradient during an increase in stroke volume caused by dobutamine infusion.

VII. POST-CATHETERIZATION CARE

A. Sheath removal. The sheath is removed once the procedure is complete. Adequate local anesthesia should be reinjected if the previously given dose has lost its efficacy. After the sheath is removed, hemostasis is generally obtained with direct manual pressure of the fingertips over the pulse, without sterile gauze to obscure the view. Pressure is held for approximately 20 minutes (about 3 minutes for each French size) until there is no bleeding. Manual pressure remains an important technique due to low cost, good safety profile (complication rate < 0.23%), short learning curve, and ability to be employed despite femoral artery dissection, significant peripheral vascular disease, or a low stick. To shorten the time of manual pressure, hemostatic pads can be used. These products are impregnated with a procoagulant mixture that causes local vasoconstriction and potentiates clot formation. Care must be taken to intermittently allow adequate blood flow to the distal extremity. It is, therefore, best if one can directly visualize the extremity to assess its color. If both arterial and venous sheaths are present, it is best to remove the venous sheath first and then obtain hemostasis before removing the arterial sheath. In patients with severe aortic stenosis or significant left main CAD, laboratory personnel should be prepared to rapidly manage a vagal episode, which can be life threatening in these situations. Adequate administration of anesthesia before removal of the sheath decreases the chance of a vagal reaction.

Bed rest is generally required for 6 hours after a femoral sheath is removed, although some operators require 1 hour for each French size. In fact, 2 hours is a sufficient period of bed rest for 5F sheaths. Two hours of keeping the arm straight is necessary after a brachial or radial procedure. During the postprocedure observation period, it is necessary to monitor the HR, temperature, blood pressure, urine output, distal pulses, and the access site (for pain, bleeding, or hematoma). Using sandbags over the groin site is discouraged. Before discharge, it is best to have the patient ambulate under observation. Specific discharge instructions should include the possibility of late access site bleeding and the need to hold pressure and call for emergency help.

Intravenous fluids are often given after a cardiac catheterization. The osmotic load of the contrast dye can cause a large diuresis. Intravenous fluids (e.g., normal saline at 100 mL/h for several hours) can prevent volume depletion. Care should be taken in patients with a history of congestive HF, in whom liberal intravenous fluids could contribute to pulmonary edema.

B. Compression/closure devices. The use of femoral artery closure devices offers the advantages of improved patient comfort, potentially lower complication rates, early sheath removal, and early hospital discharge, and anticoagulation may be continued without interruption in some patients. The currently available products include compression devices such as the FemoStop (RADI Medical Systems) and the C clamp, biosealants (Duett, vascular solutions), collagen plugs (Vasoseal; Datascope), vascular sandwiches (Angioseal; Daig), and percutaneous sutures (Perclose, Prostar, and Techstar; Abbott).

1. The **FemoStop** is a pneumatic compression device that can be used for holding pressure in cases of prolonged bleeding. The **C clamp** is a mechanical clamp that can also be used for holding prolonged pressure. If either of these devices is employed, direct supervision of the patient is required.
2. **Biosealant** (Duett) devices consist of a procoagulant mixture of collagen and thrombin that is deployed in the tissues surrounding the arterial puncture site through a balloon catheter. This device allows early ambulation. The disadvantages of this device include delayed reuse of the arteriotomy site (repeat arterial puncture cannot be performed for about 3 months) and possibility of infection due to the foreign material introduced; it can also be cumbersome to deploy, and in rare cases, inadvertent deployment of the procoagulant mixture into the femoral artery may result in arterial occlusion requiring surgical intervention.
3. The **Angioseal** (St. Jude/Kensey Nash) hemostatic puncture closure device can be used to obtain hemostasis in an uncomplicated femoral procedure if an 8F or a smaller sheath was used. Before deploying the Angioseal, it is advisable to obtain an angiogram of the femoral artery to ensure that the entry site of sheath is above the bifurcation of the common femoral artery. It is available in 6F and 8F sizes. A biodegradable collagen plug is deployed at the femoral artery puncture site using a guidewire and special sheath. No manual pressure is required, and ambulation can begin after 1 hour. The Angioseal device is user friendly due to its ease of deployment and general reliability. The disadvantage of this device is the introduction of foreign material that could be a potential source of infection, and repeat arterial puncture cannot be performed at the same site for about 45 to 60 days.
4. The **Vasoseal** (Datascope) is a collagen plug that is placed over the femoral artery puncture site. It comes in several sizes; to determine the appropriate size, it is necessary to place a depth marker on the needle during the initial arterial puncture. Ambulation can begin 1 hour after the placement.
5. The **Perclose** (Abbott) is a percutaneous vascular suture device that allows immediate ambulation (of course, after the effects of any sedation given during the procedure have worn off). Before its use, a 35°-RAO view of the right femoral artery should be taken to ensure that the sheath has been placed above the femoral artery bifurcation. The device is currently available in 6F, 8F, and 10F sizes. Other improved devices are likely to be available in the near future.
6. The **StarClose Vascular Closure System** (Abbott) is a percutaneous vascular closure device that employs a nitinol clip. Before its use, a view of the right femoral artery should be taken to ensure that the sheath has been placed above the femoral artery bifurcation. The device is delivered through a sheath onto the arteriotomy site, and the clip takes hold of the tissue in a circular manner and closes off the arteriotomy site.

VIII. COMPLICATIONS

A. Death. There is a 0.1% risk of death from LHC. This risk is substantially higher in patients undergoing urgent catheterization for acute coronary syndromes. In addition,

patients with left main CAD, severe aortic stenosis, or severe left ventricular dysfunction are known to be patient subgroups with a particularly increased risk. Advanced age increases the risk of death.

B. Myocardial infarction. There is a 0.05% risk of MI from LHC. MI can result from coronary dissection, disruption of a preexisting atheromatous plaque, and a large air embolus or a thrombus. Patients with acute coronary syndromes have a higher risk of MI.

C. Stroke. Stroke occurs in 0.05% of catheterizations. There is a risk of stroke from an inadvertent air embolus or thrombus. The presence of aortic atheroma is a risk factor for embolic complications. Dislodgement of atheromatous debris in the aorta can lead to a stroke. This risk can be minimized by the use of 260-cm exchange wires for catheter changes in patients with known severe aortic disease.

D. Coronary artery dissection. Engagement of the coronary arteries can rarely cause dissection. It is most often due to the injection of contrast through a catheter that is not coaxial to the coronary artery, causing rupture of a preexisting plaque, or placement of the catheter too deeply into the coronary artery (so-called deep throating). Particular caution should be used with Amplatz catheters. In cases of left main coronary artery dissection, a stent can be placed emergently and the patient can be placed on peripheral cardiopulmonary support until the surgical team can be mobilized.

E. Coronary artery spasm. Engagement of the coronary arteries, in particular the RCA, can cause spasm. This is best treated with withdrawal of the catheter. Subsequent reengagement and administration of intracoronary nitroglycerin (100 to 200 μg) may also be necessary for more rapid resolution of spasm.

F. Renal failure. Contrast dye can precipitate renal failure in any patient, although certain patients (those with elevated creatinine, diabetes, proteinuria, or dehydration) are at higher risk. Adequate prehydration with normal saline can reduce this risk. In some cases (especially in diabetics with renal insufficiency and those with renal artery stenoses), patients may need to be admitted to the hospital for hydration with 0.45% saline for several hours before the LHC to minimize risk of contrast-induced nephrotoxicity. The use of the antioxidant *N*-acetylcysteine (600 mg orally twice daily) before and after exposure to radiocontrast along with 0.45% saline prevented the decrease in renal function in patients with chronic renal insufficiency exposed to nonionic low-osmolality contrast agent. This study, however, enrolled only 83 patients. Other studies have examined the role of sodium bicarbonate infusions in preventing contrast-induced nephropathy. Several small studies have shown benefit with the use of sodium bicarbonate infusions (3 ampules of sodium bicarbonate in 1 L normal saline, infused at 3 mL/kg/h for 1 hour before procedure and 1 mL/kg/h during the procedure and for 6 hours following) or sodium bicarbonate plus *N*-acetylcysteine in preventing contrast-induced renal function. In a study of 129 patients with serum creatinine concentrations of 1.5 to 3.5 mg/dL who underwent coronary or aortofemoral angiography, use of the iso-osmolar, dimeric, nonionic contrast medium iodixanol was associated with decreased risk of nephropathy compared with the low-osmolar, nonionic, monomeric contrast medium iohexol. **The best way to minimize contrast-induced renal failure is to limit the amount of dye used**. Using < 30 mL of contrast dye dramatically reduces the incidence of renal failure in even the highest risk patients. Biplane cineangiography can maximize the amount of information obtained with each view.

G. Emergency CABG. There is a risk of needing emergency CABG as a complication of the catheterization (e.g., dissection of the left main coronary artery). There is also the possibility of identification of critical disease, such as severe left main CAD, that may prompt emergency CABG as the most expedient treatment.

H. Arrhythmias. A risk of ventricular fibrillation (0.5%) exists with catheterization. This rhythm is treated with electrical defibrillation. In particular, overinjection of contrast into the RCA can cause ventricular fibrillation. Contrast dye (less so nonionic dye) can cause transient bradycardia, best dealt with by having the patient cough and by minimizing the amount of dye injected with each angiographic procedure.

I. **Heart failure.** The osmotic load of contrast dye can put a patient with diminished cardiac or renal function into overt pulmonary edema. In patients with severe cardiac or renal disease, injection of contrast should be limited, and the use of nonionic, low-osmolar dye should be considered.

J. **Vagal reaction.** If a patient develops hypotension and/or bradycardia, a vagal reaction should be considered. It is a common occurrence when local anesthetic is being administered or when the sheath is being removed. Atropine 1 mg IV should be available and given in these situations. Adequate anesthesia can help prevent such reactions. In a patient with severe aortic stenosis or left main CAD, a vagal reaction can start a downward spiral that leads to death. Levophed (about 10 μg) should always be available and used immediately in such cases of hypotension.

K. **Vascular**

1. **Femoral.** Pseudoaneurysms, arteriovenous fistulas, arterial thrombosis, and peripheral emboli are possible vascular complications. Careful technique can minimize these events. In particular, paying attention to puncture location and obtaining adequate hemostasis after sheath removal are the best ways to decrease vascular complications. For example, smaller sheaths (5F) are preferred in patients with significant peripheral vascular disease. Frequent aspiration and discarding of blood from the arterial sheath, followed by gentle flushing, is useful. If an attempted cannulation is unsuccessful but an arterial puncture has been made, the needle should be withdrawn and adequate manual pressure held (about 5 minutes). If a venous puncture has been made inadvertently, the needle should be removed and pressure held (for about 3 minutes). Proceeding directly to arterial puncture without removing the needle and holding pressure increases the chance of arteriovenous fistula formation. If a venous puncture is planned, it should be made at a site lower than the arterial puncture site. Bruits should be auscultated both before and after the procedure. A new bruit may indicate a vascular complication. **Ultrasound** is an essential part of managing groin complications. If there is a large pseudoaneurysm present, surgery may be required after a trial of ultrasound-guided compression. Percutaneous injection of thrombin into the pseudoaneurysm has proven to be a more effective alternative to compression. Small pseudoaneurysms (< 2 cm) tend to close spontaneously but should be followed by serial ultrasound examinations. An arteriovenous fistula that does not close spontaneously in 2 to 4 weeks may require surgical repair.
2. **Brachial/radial.** When using an upper extremity approach, blood pressure should first be checked in both arms. If there is a difference in blood pressure between the arms, peripheral vascular disease should be suspected and the side with the higher blood pressure should be used. For a radial approach, an Allen test must be performed to assess the patency of collateral ulnar circulation. The rate of vascular complications such as thrombosis is higher with the upper extremity approach than with the femoral approach.

L. **Bleeding.** Access site bleeding can be significant. If there is a great deal of oozing around the sheath, it can be exchanged for a sheath 1F size larger. Adequate manual pressure is usually sufficient to stop bleeding after sheath removal. It is a typical practice to check the activated clotting time in patients who had been on heparin before the procedure and only proceed with sheath removal if the clotting time is below 160 seconds. Some institutions use protamine (1 mg/100 IU heparin) to reverse heparinization, but this exposes the patient to the potential for allergic reactions to protamine (namely, hypotension). Even more concerning is **retroperitoneal bleeding**. If a patient complains of severe back pain after a catheterization, this should be considered. An unexpected drop in hemoglobin after a catheterization should also raise this possibility. Obese patients, in particular, can have a major bleed without obvious external signs. Noncontrast computed tomography scan of the abdomen and pelvis can diagnose a retroperitoneal bleed, but it is important to assess the patient's clinical stability before sending them to such a study. Patients who have developed a documented retroperitoneal hematoma or are suspected of having this complication are monitored

closely in an intensive care unit, often with continuous blood pressure assessment using an arterial line and receive aggressive volume resuscitation with fluids and blood products until self-resolution with reversal of anticoagulation or definite treatment.

M. Infection. There is a risk of infection, as with any invasive procedure. This risk can be minimized with proper attention to sterile technique. There is usually no need for prophylactic antibiotics. However, some operators do give antibiotics after use of a percutaneous vascular suture device in patients who are at elevated risk for infection, such as obese or diabetic patients. Endocarditis prophylaxis for patients with valvular heart disease or prosthetic valves is unnecessary.

N. Neuropathy. There is a slight risk of damage to the femoral nerve from inadvertent puncture. Femoral hematoma (or retroperitoneal bleeding) can also cause compromise of the femoral nerve. Function usually improves with time, but complete recovery can take several months.

O. Allergy. As discussed above, contrast dye can cause adverse reactions, ranging from hives to anaphylaxis. Severe anaphylactoid reactions to contrast dye occur in about 0.1% of cases. Local anesthetics can also cause problems due to specific allergies to the amide or ester component or to the preservative. A variety of agents are available. Procaine (an ester agent), lidocaine (an amide agent), and bupivacaine (a preservative-free amide agent) are alternative agents.

ACKNOWLEDGMENTS: *The author thanks Drs. Saif Anwaruddin, Niranjan Seshadri, and Deepak L. Bhatt for their contributions to previous editions of this chapter.*

Percutaneous Coronary Intervention

I. INTRODUCTION

A. Coronary atherosclerosis may result in a flow-limiting stenosis that leads to myocardial ischemia and/or myocardial infarction (MI). Andreas Gruentzig first managed these lesions percutaneously on September 16, 1977, when he advanced a fixed-wire, distensible balloon across a stenosis in the mid–left anterior descending (LAD) artery and briefly inflated it to 6 atm (90 psi). This procedure was termed percutaneous transluminal coronary angioplasty (PTCA). With the advent of stents and other therapeutic coronary devices, these procedures are now more broadly termed percutaneous coronary intervention (PCI). It is estimated that more than 1 million PCI procedures are completed in the United States and approximately 2 million worldwide annually.

B. The field of interventional cardiology continues to rapidly evolve, as a result of many important advances in equipment, strategies, and adjunctive medication. These advances have been paralleled by a concomitant improvement in the safety and efficacy profile of PCI. The assimilation of a large body of basic and clinical research encompassing all areas of interventional cardiology continues to redefine the standard of care paradigm.

II. PCI INDICATIONS

A. Central tenet. Although there is no substitute for sound clinical judgment, PCI is generally reserved for patients in whom there is an objective demonstration of myocardial ischemia or symptoms as well as angiographic demonstration of obstructive coronary disease. PCI may not be indicated for asymptomatic or mildly symptomatic patients who have only a small area of viable or jeopardized myocardium, have no objective evidence of myocardial ischemia, have other life-limiting disease processes, or have lesions that have a low likelihood of success (Tables 65.1 and 65.2).

B. ST-segment elevation myocardial infarction (STEMI). Primary PCI should be the preferred treatment strategy for patients presenting with STEMI to a facility experienced with and capable of performing PCI. Randomized trials have demonstrated that clinical outcomes are improved when such patients are emergently transferred to centers able to perform primary PCI as opposed to therapy with thrombolytics—despite a significant delay (mean time of 44 minutes) in time to therapy due to transport. This seems especially true of patients presenting 3 to 12 hours after symptom onset, where the superiority of primary PCI becomes clearly evident. In those presenting within 3 hours of symptom onset, mortality data would suggest that either therapy is equally efficacious in appropriate candidates. **For a more thorough discussion of the management of STEMI, please refer to Chapter 1**.

C. Non–ST-segment elevation acute coronary syndrome (NSTEACS). Unstable angina and non–ST-segment elevation myocardial infarction (NSTEMI) are considered part of the spectrum of NSTEACS. Given that individual patients presenting

TABLE 65.1 Standard Prepercutaneous Coronary Intervention Evaluation

History

- Symptoms (angina, dyspnea, paroxysmal nocturnal dyspnea, syncope)
- Previous MI
- Previous cardiac interventions (PCI, CABG)
- Comorbidities (diabetes mellitus, hyperlipidemia, hypertension, etc.)

Medications (glucophage, statins, aspirin, thienopyridines, etc.)

Allergies (contrast dye, latex, etc.)

Physical exam (murmurs, jugular venous pressure, pulses, bruits, edema)

Laboratory data (creatinine, potassium, hemoglobin, platelets, INR)

Other tests (ECG, echocardiogram, stress tests)

Informed consent including risks, benefits, alternatives

CABG, coronary artery bypass grafting; ECG, electrocardiogram; INR, international normalized ratio; MI, myocardial infarction; PCI, percutaneous coronary intervention.

TABLE 65.2 Considerations for Every Percutaneous Coronary Intervention

Review clinical and angiographic risk factors

Develop strategy and anticipate problems

- Surgical backup
- Access
- Anticoagulation and antiplatelet therapy
- Consider diagnostic adjuncts (e.g., PA line)
- Consider therapeutic mechanical adjuncts (e.g., IABP)
- Guidewire
- Device (e.g., angioplasty, stent)
- Closure of vascular access site
- Post-PCI destination (telemetry ward, CICU)

CICU, cardiac intensive care unit; IABP, intraaortic balloon pump; PA, pulmonary artery; PCI, percutaneous coronary intervention.

with unstable angina/NSTEMI are at widely varying risk for subsequent morbidity and mortality, early and aggressive risk stratification including cardiac catheterization with subsequent percutaneous or surgical revascularization (rather than noninvasive stress testing) is recommended. This recommendation is supported by a number of clinical trials comparing an early invasive to delayed conservative strategy. **For a more thorough discussion of the management of NSTEACS, please refer to Chapter 2.**

D. Chronic stable angina. It is estimated that > 85% of all PCI procedures are performed in the elective setting for chronic stable angina. While recent trials have

questioned the mortality benefit of PCI or coronary artery bypass grafting (CABG) over optimal medical therapy in stable coronary artery disease (CAD), revascularization still remains the most rapidly effective treatment strategy for patients with angina. **For a more thorough discussion of the management of stable CAD, please refer to Chapter 6.**

III. CONTRAINDICATIONS. The only absolute contraindication to PCI is significant active bleeding, given the absolute need for procedural anticoagulation and continued dual antiplatelet therapy (DAT). Relative contraindications include a bleeding diathesis, unsuitable or high-risk coronary anatomy (e.g., chronic total occlusion in the absence of ischemia or diffuse distal disease), recurrent in-stent restenosis (ISR), and a short life expectancy because of a comorbid condition.

IV. PROGNOSIS. A patient's clinical status and coronary angiogram are powerful predictors of outcome. Certain clinical and angiographic variables have repeatedly been associated with adverse events (Table 65.3).

V. ANGIOGRAPHIC/PROCEDURAL/CLINICAL SUCCESS. Angiographic success is defined as a residual stenosis < 50% with PTCA or < 20% with stenting and is achieved in 96% to 99% of patients. The definition of procedural success is angiographic success without major in-hospital complications (i.e., death, CABG, or MI). Clinical success is defined as procedural success with relief of the symptoms and signs of myocardial ischemia.

VI. COMPLICATIONS

A. The incidence of complications (death 0.5% to 1.4%, periprocedural MI [defined by creatine kinase-myocardial band, CK-MB, elevation more than three times the upper limit of normal] up to 8%, and emergency CABG surgery 0.2% to 0.3%) has consistently decreased over the past 20 years with the advent of stents, new and more effective antiplatelet therapies, improved equipment, and increasing reliance upon evidence-based strategies.

B. **Abrupt closure** is the most common cause of a major adverse cardiac event (MACE) and typically occurs within 6 hours of intervention. The most common cause of abrupt

TABLE 65.3 Clinical and Angiographic Predictors of Adverse Outcomes

Clinical predictors	Angiographic predictors
• Older age	• Thrombus
• Unstable angina	• Bypass graft
• Acute MI	• Left main trunk
• Cardiogenic shock	• Lesion > 20 mm in length
• CHF	• Excessive tortuosity of proximal segment
• Left ventricular function	• Extremely angulated lesions > 90°
• Multivessel coronary disease	• Total occlusion > 3 months old and/or bridging collaterals
• Diabetes mellitus	• Inability to protect major side branches
• Renal impairment	• Degenerated vein grafts with friable lesions
• Peripheral vascular disease	• Unprotected left main trunk
• Small body size	

CHF, congestive heart failure; MI, myocardial infarction.

closure is suboptimal stent expansion or dissection followed by thrombus, spasm, and side branch occlusion. In the mid-1980s, the risk of abrupt closure approached 5%. The common use of periprocedural glycoprotein (GP) IIb/IIIa and/or direct thrombin-inhibiting anticoagulants and stent deployment has reduced this risk to < 1% in modern practice. Risk factors for abrupt closure include presentation with acute MI, poor coronary flow postintervention (i.e., less than Thrombolysis in Myocardial Ischemia [TIMI] II), complex lesion morphology (i.e., class C lesions), and suboptimal result as judged by angiography or intravascular ultrasound (IVUS) imaging.

C. **Atheroembolism and thromboembolism** probably occur to varying degrees in all interventions, but are most frequently encountered in cases involving degenerated vein grafts, in patients presenting with acute coronary syndromes (ACSs), and in cases using directional/rotational atherectomy. Distal embolization can result in "no-reflow" (decreased coronary flow), abrupt closure, and periprocedural MI. Thromboembolism can be minimized by using aspiration catheters (e.g., Pronto, Export, Extract) or rheolytic thrombectomy (Possis AngioJet) to remove thrombus as well as routine anticoagulant and antiplatelet therapy. The prevention of atheroembolus, most often encountered during vein graft intervention, is frequently addressed with the use of a filter device (e.g., FilterWire EZ or PercuSurge GuardWire) or proximal flow occlusion device (e.g., Proxis) to trap and remove the debris before it reaches the distal vascular bed. Intracoronary administration of vasodilators such as adenosine (36 to 72 μg repeatedly), nitroprusside (50 to 200 μg), and verapamil (200 μg) has been shown to prevent and manage no-reflow, but have no effect in preventing CK-MB elevation.

D. **Coronary perforation** is typically identified using the Ellis classification: Type I: extraluminal crater without extravasation; Type II: pericardial or myocardial blush without contrast jet extravasation; Type III: extravasation through frank (> 1 mm) perforation; Type III cavity spilling: perforation into an anatomic chamber, coronary sinus, etc. Coronary perforation is estimated to occur in 0.1% to 1.14% of routine PCI cases, 0.25% to 0.70% of cases using directional atherectomy, up to 1.3% of cases using rotational atherectomy, 1.3% to 2.1% of cases using extractional atherectomy, and 1.9% to 2.0% following excimer laser angioplasty. Contrast extravasation is typically evident in the majority of cases at the time of PCI; however, up to 20% of cases can present several hours after the procedure and are frequently due to hydrophilic wire perforation of a small vessel. Treatment usually requires prolonged balloon inflation (consider a perfusion balloon) and reversal of anticoagulation. Transthoracic echocardiography should be immediately performed in the setting of clinical instability in order to evaluate for the presence of a pericardial effusion and/or tamponade, in which case urgent pericardiocentesis is required. Covered stents, coils, or surgical repair may be required for definitive management.

E. **Vascular access site complications** remain the most common complication of PCI and occur in up to 5% of patients. The most common are blood transfusion (3%), arteriovenous fistula (< 2%), pseudoaneurysm (up to 5%), acute arterial occlusion (< 1%), and infections (< 0.1%). Shorter anticoagulation regimens, weight-adjusted heparin, use of bivalirudin, early sheath removal, vigilant monitoring of activated clotting times (ACTs), smaller sheaths, and avoidance of routine venous sheath insertion have all contributed to a reduction in complications. Stopping heparin after PCI and substituting clopidogrel for warfarin has also resulted in a reduction of bleeding and coronary complications.

F. **Contrast-induced nephropathy** occurs in 3% to 7% of patients, and the risk increases tenfold for patients with serum creatinine > 2.0 mg/dL, especially in the presence of diabetes mellitus. Data regarding methods to prevent renal failure are not definitive, but the most proven benefit is seen with conservative contrast utilization. In addition, use of biplane imaging can significantly reduce the amount of contrast required. Numerous studies have provided mixed results on the benefits of saline infusion before catheterization, administration of *N*-acetylcysteine (NAC) 600 mg po or IV bid for 1 day before and after the day of catheterization, single bolus dose

NAC prior to contrast load, using nonionic contrast dye, and infusion of a sodium bicarbonate solution.

G. Contrast-mediated reactions can be serious. Anaphylactoid reactions occur in 1% to 2% of patients receiving iodinated contrast. These reactions can be severe in 0.10% to 0.23% of patients. The risk of a severe reaction can be effectively decreased by using nonionic contrast, preprocedural corticosteroids (i.e., prednisone 40 to 60 mg) given the evening before and the morning of the procedure, and the use of H_1 and H_2 blockers. If a patients presents for emergent PCI (i.e., STEMI) without having undergone preprocedural steroid preparation, the emergent administration of hydrocortisone 100 mg IV and diphenhydramine 25 to 50 mg IV is reasonable and is shown to be safe in small series. In patients undergoing an elective procedure, caution is prudent and a full premedication regimen is recommended.

H. Stent thrombosis (ST) is discussed later in Section **XI.D**.

VII. EXPERIENCED OPERATORS/CENTERS

A. Procedural volume is an important predictor of PCI complications. **Elective PCI** should be performed in high-volume centers (> 200 interventions per year, with an ideal minimum of > 400 cases per year) by operators with an acceptable annual volume (> 75 cases per year) at institutions with fully equipped interventional laboratories, experienced support staff, and an on-site cardiovascular surgical program. **Primary PCI for STEMI** should be performed in similarly experienced/skilled centers by operators who perform > 75 elective cases per year and intervene on at least 11 cases of STEMI per year. **Elective PCI should not be** performed by low-volume operators (< 75 cases per year) in low-volume centers (< 200 cases per year), regardless of the availability of on-site cardiothoracic surgery, because of the increased risk of suboptimal outcomes. Referral to a larger regional center is recommended in this situation.

B. In cases of STEMI, there is an inverse relationship between the number of primary angioplasty procedures performed by an operator and in-hospital mortality. The data suggest that both door-to-balloon time and in-hospital mortality are significantly lower in institutions that perform a minimum of 36 primary angioplasty procedures per year.

VIII. SURGICAL BACKUP.

Emergency surgical intervention is a rare event and is required in 0.3% to 1.0% of cases of PCI, usually because of complications that cannot be addressed percutaneously or to provide urgent hemodynamic support. The most common reasons for emergency CABG surgery are dissection resulting in acute vessel closure, perforation, inability to retrieve a stent or other device, or aortic dissection. Emergency CABG after PCI has a mortality rate of 15% and periprocedural MI rate of 12%. The internal mammary artery may not be harvested, and surgery should not be delayed due to abciximab. Perfusion balloons may temporize a life-threatening perforation or dissection, and an intraaortic balloon pump (IABP) can minimize ischemic injury and stabilize hemodynamics. Data from the Atlantic Cardiovascular Patient Outcomes Research Team (C-PORT) and Primary Angioplasty in Acute Myocardial Infarction with No Surgery On-Site (PAMI-No SOS) trials suggest that **primary PCI for STEMI** can be safely and effectively performed in centers that **do not** perform elective PCI and do not have on-site cardiac surgery capabilities if they implement a carefully developed and proven strategy capable of rapid and effective PCI (including an experienced operator with > 75 total PCIs and at least 11 primary PCIs for STEMI per year) with a predetermined transfer plan to a nearby center with on-site surgical backup.

IX. SHEATHS, GUIDES, AND WIRES

A. Typical arterial access involves placing a 6F to 8F short sheath in the common femoral artery using the modified Seldinger technique. Using fluoroscopic guidance when entering the femoral artery above the inferior margin of the femoral head but below the pelvic rim increases the likelihood of entering the common femoral artery

at a compressible site above the common femoral artery bifurcation and below the inferior epigastric artery. The superficial/profunda femoral artery bifurcation is best seen in the ipsilateral 30° to 40° projection. The brachial and radial arteries can accommodate up to 7F and 6F sheaths, respectively. Ulnar artery and digital arch patency should be confirmed via the Allen test in case the radial artery becomes occluded (approximately 5%). Radial access improves hemostasis and earlier ambulation but increases radiation exposure, lengthens the procedure, and limits the choice of coronary equipment (6F compatible).

B. Larger guide size (7F or 8F) provides extra support and permits the use of larger rotational atherectomy burrs and use of kissing balloons. For straightforward lesions, a 6F system is typically adequate. The XB (extra backup) and Amplatz guiding catheters provide good support; the Amplatz guide is especially effective in cases of an acutely angled left circumflex artery, anomalous left circumflex artery originating from the right sinus, very anteriorly originating right coronary artery, or a tortuous/calcified right coronary artery. The Amplatz guide catheter is also the most likely catheter to traumatize the ostial/proximal coronary artery in inexperienced hands due to its tendency to deeply engage the vessel.

C. The coronary lesion is initially crossed with a 0.014" diameter coronary wire, which serves as a "rail" for devices such as balloons and stents. The choice of a wire depends on the wire tip's stiffness, lubriciousness, and support characteristics. Stiff tips are helpful to penetrate chronic total occlusions but increase the risk of vessel dissection or perforation. Hydrophilic wires are quite slippery and may be used to cross tortuous high-grade lesions, but can easily cause dissection or end-vessel perforation. Support wires also typically have stiffer tips and are primarily used as a supportive rail to deliver coronary equipment through tortuous vessels. Generally, most operators routinely use a "workhorse" wire (i.e., Prowater or Balance MiddleWeight) and have "favorite" stiff (e.g., Miracle Bros series), hydrophilic (e.g., Whisper and Pilot series), and support (e.g., GrandSlam and Balance HeavyWeight) wires for use in appropriate situations. Both short (approximately 180 cm) and long (approximately 300 cm) wires are available. Most operators prefer the routine use of a rapid exchange (Rx) system, which uses a monorail that permits easy exchange over a short wire, although situations that require an over-the-wire system may be better served with the use of a longer wire to avoid dislodging the wire during equipment exchanges.

X. DIAGNOSTIC ADJUNCTS

A. IVUS (anatomic)

1. An IVUS catheter generates a cross-sectional tomographic image of both the lumen and the vessel wall. This complementary imaging modality can be invaluable when repeated angiographic views fail to determine the mechanism and/or significance of a coronary lesion. IVUS has proven helpful in assessing adequacy of coronary stent deployment, mechanism of ISR (neointimal hyperplasia versus inadequate stent expansion), a coronary lesion at a location difficult to image by angiography, a suboptimal angiographic result after PCI, coronary allograft vasculopathy after cardiac transplantation, coronary calcium when considering rotational atherectomy, and plaque location/circumferential distribution to guide directional coronary atherectomy (DCA). Further, IVUS can be indispensible in assessing the appropriate vessel size, especially during ACS when factors such as thrombus and vasoconstrictive substances can lead to significant stent undersizing.
2. IVUS provides anatomic, not physiologic, information. However, a lumen area < 4.0 mm^2 in the proximal LAD, left circumflex, or right coronary artery or < 6.0 to 7.0 mm^2 in the left main trunk suggests the presence of a hemodynamically significant lesion.

B. Optical coherence tomography (OCT). Similar to IVUS, OCT images are obtained by passing the catheter over a guidewire in the coronary artery. The catheter

acquires images during an automated pullback over 5.6 cm and requires the clearance of blood in the vessel, thereby necessitating a 15 to 18 cc contrast injection with each acquisition. In comparison with IVUS, it provides much greater image resolution but a more shallow penetration. Outside of research use, OCT is finding a place in the clinical armamentarium. The superior image quality allows an evaluation of stent apposition, poststent dissection, and analysis of plaque characteristics and plaque rupture. Recently, investigators have used OCT to evaluate endothelial stent coverage, which in the future may allow a further tailoring of antiplatelet therapy at the patient-specific level. Currently, there is a paucity of clinical outcomes data using OCT, but interest in this imaging modality is gaining momentum, with supportive data likely to follow.

C. Angioscopy (anatomic). Angioscopy uses a balloon-tipped catheter with a fiber optic viewport at the distal tip that allows direct visualization of the lumen. Angioscopically evident thrombus has been shown to be angiographically silent in up to 50% of patients. This imaging modality is only used for research purposes.

D. Coronary flow reserve (CFR) (physiologic)

1. A 0.014" wire capable of measuring coronary flow velocity permits assessment of epicardial and microvascular resistance. This information is helpful in determining whether a moderate-grade coronary stenosis (i.e., 30% to 70% stenosis) is hemodynamically significant. The ratio of hyperemic to basal flow is known as the CFR and is determined by giving an intracoronary vasodilator such as adenosine (36 to 64 μg). A normal CFR is 3 to 5. A CFR < 2.0 is abnormal and is consistent with a flow-limiting epicardial stenosis or increased microvascular tone.
2. The effect of the microvasculature can be eliminated by measuring the CFR in two vessels: the lesion-containing vessel and a normal-appearing vessel. This allows calculation of the relative coronary flow reserve velocity ($rCFR = CFR_{target}/CFR_{reference}$). A nonhemodynamically significant stenosis has an rCFR value of < 0.8 and is similar in prognostic value to negative stress testing. Unlike fractional flow reserve (FFR), CFR depends on hemodynamic and microcirculatory changes. In general, FFR is the preferred diagnostic modality for assessing the hemodynamic significance of a coronary lesion.

E. FFR (physiologic). A 0.014" wire with a pressure transducer is placed distal to a coronary stenosis and the translesional gradient measured. This allows calculation of the FFR, which is the ratio of this distal coronary pressure to aortic pressure during maximal hyperemia. A vasodilator such as adenosine (IV infusion 140 μg/kg/min or intracoronary 36 to 64 μg) is used. A coronary artery without flow-limiting coronary obstruction would have an FFR of 1.0. An FFR value of < 0.75 to 0.80 is consistent with a hemodynamically significant obstruction and positively correlates with myocardial ischemia on stress testing. Unlike CFR, the FFR reflects only the epicardial artery lesion. Prospective studies have demonstrated that an FFR-guided strategy to direct PCI of intermediate lesions results in less stents deployed, with a significant decrease in morbidity and mortality compared with an angiography-only strategy (8.4% vs. 23.9%, $p = 0.02$).

F. Pulmonary artery catheter (physiologic). A balloon-tipped Swan-Ganz catheter advanced to the pulmonary arteries allows measurement of right and left heart filling pressures as well as the cardiac output. This information can be helpful in patients presenting with cardiogenic shock, during high-risk PCI in the setting of severe left ventricular (LV) dysfunction, when there is a question of pericardial tamponade, or when the cause of hemodynamic deterioration is unclear.

XI. THERAPEUTIC DEVICES

A. Percutaneous transluminal coronary angioplasty. The coronary balloon remains the backbone of endovascular intervention, although its sole use is in decline. The initial gain in the coronary lumen achieved by balloon inflation results in localized dissection of the intima (and often the media) plus distension of the adventitia. The

dissection is covered by platelet-rich thrombus and later by new intimal layers. As a result of these inevitable dissections, the abrupt closure rate is 4% to 7%, although the use of GP IIb/IIIa inhibitors has reduced this rate. The 6-month angiographic restenosis rate of 30% to 40% is another downside to PTCA. Furthermore, the risk of cardiac morbidity, including anginal symptoms, progressively increases with subsequent episodes of ISR following balloon angioplasty. It is recommended that patients determined to have significant ISR following PTCA should be strongly considered for coronary stent implantation.

PTCA alone may still have utility in patients presenting with ACS found to have multivessel disease suitable for urgent/emergent CABG (e.g., PTCA alone rapidly restores patency to the infarct-related artery but may allow a break in the need for antiplatelet therapy, thereby allowing the patient to proceed to surgery without delay). Even in these situations, however, aspiration thrombectomy alone may be preferred if it provides reasonable flow to the infarct artery in order to avoid the risk of mechanical complications with PTCA, such as dissection or perforation, that would require stent deployment.

B. Bare-metal stents (BMSs)

1. Present-day coronary stents are flexible, laser-cut and polished, balloon-mounted, and expandable, slotted tubes composed of either stainless steel or metal composites such as cobalt–chromium. They have proven effective in treating dissections and reducing the incidence of abrupt closure, emergency CABG (< 1%), and restenosis. First implanted in 1986 and used for emergency treatment of coronary dissection after angioplasty, the early era of the intracoronary stent placement was plagued by high rates of subacute closure despite intensive anticoagulation regimens that often led to bleeding complications and prolonged hospitalization. Evolution of stent design and interventional technique led to a rapid reduction in procedural complication rates and marked improvement in the ease of stent delivery and deployment.
2. Although subacute vessel closure may still occur in up to 3% of cases following stent implantation, by providing a scaffold and reducing elastic recoil, BMSs have reduced the published rates of restenosis from > 50% following PTCA alone to 20% to 30%. **Restenosis risk is increased in patients with small reference vessel size, smaller postprocedural luminal diameter, or high degree of residual stenosis, long lesion length, diabetes, lesion location in the LAD artery, and presence of untreated edge dissection during the procedure**. Furthermore, while stents reduce the rate of restenosis and repeat revascularization as compared with PTCA alone, they have not been shown to reduce the incidence of death or MI.

C. Drug-eluting stents (DESs). The Achilles heel of BMS has been ISR. Antiproliferative agents such as sirolimus, paclitaxel, zotarolimus, and everolimus arrest cell division during the mitotic growth phase. The use of polymers to coat these agents onto a stent's surface and provide controlled, local drug delivery has dramatically reduced neointimal hyperplasia and thereby ISR. These DESs, introduced generally in 2003, were rapidly embraced and occupied almost 90% of the stent market by 2005. Concerns about ST and the need for prolonged DAT (discussed below) have since tempered their use, and DESs now account for approximately two-thirds of stents that are deployed. There are a number of DESs available, with various studies supporting their clinical use. While a thorough discussion of trial data is outside the scope of this chapter, a brief overview is summarized below.

1. **Cypher (Cordis, NJ) sirolimus-eluting stent (SES).** The Cypher DES makes use of the BxVelocity stainless steel platform. The pivotal Randomized Study with the Sirolimus-Coated Bx Velocity (RAVEL) trial randomized 238 patients with simple lesions to SES versus a standard BMS. At 1 year, the angiographic restenosis rate (> 50%) was 0% in the SES group and 26.6% in the BMS group. Five-year follow-up of the US-approved SIRIUS trial of patients with complex coronary disease revealed durable reductions in target lesion revascularization

(TLR) compared with BMS (9.6% vs. 24.7%), with negligible differences in death and MI. A number of trials and meta-analyses have highlighted the benefits of SES, and it remains in use today. Given its stainless steel platform, this stent is often used in heavily calcified lesions or those that require high radial strength. Unfortunately, Johnson & Johnson has announced plans to discontinue production.

2. **Taxus (Boston Scientific, MA) paclitaxel-eluting stent (PES).** The Taxus DES was initially supported by the Express platform and more recently by the thinner Liberte stainless steel BMS platform. The PES was developed almost simultaneous to the SES and first studied in the TAXUS I trial in a group of patients with simple lesions; at 6 months, the PES group displayed no significant angiographic restenosis. The TAXUS IV trial compared 1,314 patients with complex native vessel coronary disease randomized to either PES or BMS and demonstrated significant reduction in TLR (9.1% vs. 20.5%) with PES at 5-year follow-up, with negligible differences in death and MI.
3. **SES versus PES.** A number of studies, some of which have been randomized, have compared SES and PES in various patient groups. Most of these trials have found that SES is superior to PES. The SIRTAX trial randomly assigned 1,012 patients presenting to the catheterization laboratory to either SES or PES and demonstrated a significant reduction (10.8% vs. 6.2%) in the rate of MACE, primarily due to reduction in the rate of TLR observed in the SES group. Similarly, in a meta-analysis of almost 9,000 patients, SES was associated with less TLR (hazard ratio [HR] 0.74) and ST (HR 0.66) than PES, with no significant difference in death or MI, at 2 years of follow-up. There is a suggestion that PES performs better in patients with diabetes, although comparisons of SES and PES even in this subgroup yield lower rates of TLR with SES use.
4. **Endeavor, Resolute, and Resolute Integrity (Medtronic) zotarolimus-eluting stents (ZES).** The Endeavor DES elutes zotarolimus from a cobalt–chromium Driver stent platform. The ENDEAVOR series of trials (I to IV) have demonstrated the effectiveness of ZES in comparison with BMS, SES, and PES. Five-year follow-up of the patients randomized in ENDEAVOR II showed a significantly lower rate of TLR for ZES versus BMS (7.5% vs. 16.3%) and equivalent rates of very late ST (0.2% vs. 0.3%). The ENDEAVOR III trial was a small study of patients randomized to ZES ($n = 323$) or SES ($n = 113$) and showed significantly higher rates of total TLR (clinically and nonclinically driven, 9.8% vs. 3.5%) but nonsignificant differences in clinically driven TLR (6.3% vs. 3.5%, $p = 0.34$) for the ZES at 8 months. The ENDEAVOR IV investigators randomized 1,548 patients to ZES or PES and found a nonsignificant trend toward higher rates of angiographic late loss at 9 months (15.3% vs. 10.4%, $p = 0.284$) and TLR at 12 months (4.5% vs. 3.2%, $p = 0.228$) in the ZES group. The large-scale Patient Related Outcomes with Endeavor versus Cypher Stenting Trial (PROTECT) is currently underway. The Resolute stent makes use of the Driver platform with a newly designed polymer that allows a delayed release of the drug for out to 3 months. The RESOLUTE US trial revealed noninferiority of the Resolute in comparison with historical Endeavor controls at 1 year. The RESOLUTE AC trial revealed no significant differences in patient- or stent-related outcomes in comparison with the Xience V at 2 years, although one cause for concern is the trend toward greater ST with the Resolute (1.9% vs. 1.0%, $p = 0.077$). The Resolute Integrity stent, available only in Europe at this time, elutes zotarolimus from Medtronic's Integrity stent platform and prides itself on improved deliverability; studies are currently underway.
5. **Xience V (Abbott Vascular, CA) and Promus (Boston Scientific, MA) everolimus-eluting stent (EES).** Sold as Xience V and Promus, the EES is based on the cobalt–chromium MultiLink Vision stent platform. The SPIRIT series of trials (I to V) have demonstrated the efficacy of the Xience V EES in comparison with

the Taxus PES. The large-scale SPIRIT IV trial was powered to assess superiority of EES over PES. Recently reported 2-year follow-up revealed significantly reduced rates of target lesion failure (TLF; cardiac death, target vessel MI, ischemia-driven TLR) (6.9% vs. 9.9%), ischemia-driven TLR (4.5% vs. 6.9%), MI (2.5% vs. 3.9%), and ST (0.4% vs. 1.2%) for EES. Notably, in the diabetic subgroup at 1 year, there was no appreciable difference in TLF (6.4% vs. 6.9%). The SPIRIT V trial of EES versus PES in diabetic patients, however, suggests a benefit of EES in this group of patients (in-stent late loss at 9 months 0.19 vs. 0.39 mm, $p < 0.01$; TLF at 12 months 11.2% vs. 12.5%, $p = 0.71$; and ST 0% vs. 1.9%). Notably, though, this was a small trial (EES $n = 218$, PES $n = 106$).

6. **Large vessels.** Retrospective subgroup analysis had suggested that large vessel DES (SES and PES) provided no significant reduction in TLR compared with BMS but did result in increased rates of ST. To address this question prospectively, the BASKET-PROVE investigators randomized patients to the use of BMS, SES, or EES in lesions requiring stents 3.0 to 4.0 mm in diameter. They found statistically similar rates of death/MI with both DES and BMS, but a decrease in target vessel revascularization (TVR) with either type of DES compared with BMS at 2 years (~3.5% vs. ~9.0%). Furthermore, definite or probable ST was not significantly different between the SES, EES, and BMS groups. These data suggest that while the rate of BMS ISR in large vessels is lower than that in smaller vessels, the benefit of DES persists to further lower the rate of restenosis without a concomitant increase in the risk of ST (as long as DAT can be continued).

D. Stent thrombosis is defined as early (< 30 days), late (30 days to 1 year), and very late (> 1 year). It may be the result of stent-, procedure-, patient-, and antiplatelet therapy–related factors, and minimizing the risk of ST requires a conscious consideration of each of these issues. Compared with thrombosis of native coronary arteries, ST is associated with a higher thrombus burden and less frequent procedural success, all of which results in a much higher rate of death, recurrent MI, and recurrent ST.

1. **Stent-related factors.** Following BMS implantation, the vascular endothelium typically grows over the stent struts in 2 to 4 weeks, thereby eliminating contact between the stent and circulating platelets with a concomitant reduction in thrombotic risk. In contrast, **reendothelialization following DES implantation is significantly retarded** because of the antiproliferative effect of the coating polymer, thereby allowing for strut/platelet contact up to several years post-PCI (similar to the historical use of brachytherapy). In meta-analyses of large trials, the **overall incidence of ST is similar in both BMSs and DESs (0.5% to 1.0% per year). However, prolonged DAT is necessary in patients with DES** due to delayed endothelialization and is therefore associated with a higher risk of very late ST (approximately 0.5% per year) in patients who discontinue DAT than in patients with BMS. It is for this reason that BMS is a favored option in patients requiring PCI before major surgery or those that possess a significant contraindication to long-term antiplatelet therapy. In appropriately selected patients, however, DES is favored for its established benefits with respect to ISR and reduced need for repeat intervention.
2. **Procedure-related factors. Incomplete stent apposition to plaque/vessel wall, inadequate stent expansion (i.e., stent undersizing to the vessel), and stent-edge dissection** all increase the risk of ST. While angiography may indicate all of the above problems, stent sizing is routinely underestimated by the angiogram alone. Further interrogation of the vessel using IVUS or OCT (discussed in Sections **X.A** and **X.B**, respectively) may be necessary to optimize the chances of success and minimize the risk of ST. It is **recommended that stents be expanded to 80% of the minimal reference vessel area**. Additional risk factors for ST include long lesion length, small artery diameter, and complex lesion morphology (i.e., bifurcation stenting and chronic total occlusion).

3. **Patient-related factors.** Comorbid risk factors not only are important in assessing the relative benefit of DES but also increase the risk of ST. For instance, patients with **diabetes, impaired LV function, and renal disease** not only derive greater benefit from the antirestenotic properties of DES but also present a greater risk of ST. **Premature cessation of DAT** (due to nonadherence, need for surgery, bleeding complications, or financial considerations) as well as poor clopidogrel response (seen in up to 15% of patients) also increase the risk of ST, especially in patients treated with DES.
4. **Duration of antiplatelet therapy.** In patients with ACS, the use of 12 months of DAT is recommended for its established benefit in reducing MACE over aspirin alone. With respect to stent safety alone, however, use of 4 to 6 weeks of clopidogrel is sufficient to allow endothelialization of the BMS. For DES, numerous authors have demonstrated that cessation of DAT is a significant predictor of ST, and moreover that DES is associated with a greater risk of very late ST compared with BMS after cessation of DAT. Unfortunately, registry and small randomized trial have not proven an overall clinical benefit to prolonged DAT, although some studies have demonstrated a reduction in very late ST. Large randomized trials are currently underway to investigate the clinical conundrum of DAT duration after DES implantation. The ACC/AHA guidelines therefore recommend a minimum duration of DAT of 12 months (class I), with a consideration of DAT for > 15 months in patients with DES (class IIb).
5. Although DESs have dramatically reduced the incidence of ISR and MACE, especially in patients with diabetes and complex coronary lesions, a mounting body of evidence suggests an increased risk of late and very late thrombosis following the discontinuation of antiplatelet therapies. Therefore, **the decision to use BMS or DES in any given patient requires a thorough evaluation** of factors that may predispose the patient to premature discontinuation of DAT (which would favor BMS). In our laboratory, the use of BMS and DES is roughly equivalent.

E. Covered stents. Covered stents use a material such as polytetrafluoroethylene (PTFE), which covers the stent struts and seals off the vessel wall from the stent lumen. The Jomed covered stent has PTFE sandwiched between two Jostents. This covered stent is approved for use after coronary perforation by the Food and Drug Administration (FDA), but requires reporting of their use in this situation as a sentinel event. FDA approval can also be obtained on a case-by-case basis in patients with coronary aneurysm.

F. Cutting balloon atherectomy

1. These balloons were initially developed to create a "controlled dissection." A cutting balloon has three to four longitudinally mounted, razor-sharp atherotomes. These atherotomes cut into both plaque and vessel wall and allow vessel dilatation at a lower balloon pressure. Success in the treatment of balloon-resistant lesions led to FDA approval in 1995. Although randomized data have shown no difference between cutting balloon angioplasty and PTCA, many operators will use this device in lesions with high elastic recoil (i.e., ostial or bifurcation lesions) before DES. The AngioSculpt device consists of a balloon surrounded by a nitinol cage that prevents balloon slippage and scores the plaque. An alternative to these specialized balloons is to place a second guidewire as a "buddy" in the coronary artery, which serves as a makeshift cutting device at the lesion during balloon inflation over the first wire.
2. Cutting balloons have also found a niche in the treatment of ISR. Regular balloons often slip when inflated across these rubbery lesions. The Restenosis Reduction by Cutting Balloon angioplasty Evaluation III (REDUCE III) trial randomized 521 patients to cutting balloon or PTCA before stenting (with angiographic or IVUS guidance) and demonstrated a significantly lower rate of angiographic

restenosis in the cutting balloon before stenting group, primarily with IVUS guidance. The "buddy wire" technique may also be useful to increase friction and minimize balloon slippage in the treatment of ISR. It is important to use a second wire that does not have a hydrophilic coating in order to maximize effectiveness.

3. Care must be taken not to oversize cutting balloons, because perforation can occur. Placing these balloons through stent struts or down tortuous vessels can result in atherotome entrapment, as can a perforated balloon. These balloons should only be inflated to 6 to 10 atm in order to decrease the likelihood of balloon rupture.

G. Rotational atherectomy

1. Rotational atherectomy uses a 160,000 rpm, diamond-coated burr (i.e., drill bit) that is advanced over a 0.009" wire to the coronary lesion. The process generates microparticulate debris that embolize and may attenuate the coronary microcirculation, inducing transient myocardial stunning, periprocedural MI, and LV dysfunction in the region of the target vessel. Therefore, although limited clinical data suggest that rotational atherectomy can be safely performed in patients with depressed LV function in the hands of an experienced operator, it is not recommended.
2. Compared with plain balloon angioplasty, rotational atherectomy increases the chance of procedural success but has not been shown to reduce the risk of restenosis or MACEs in de novo or restenotic lesions. Although the use of rotational atherectomy has declined, it is recommended before stenting in patients with severely calcified lesions, undilatable lesions, chronic total occlusions, and bifurcation lesions to help ensure proper stent expansion and apposition in balloon-resistant lesions.
3. Familiarity with the device is essential. Sluggish coronary flow can occur, requiring a vasodilator such as verapamil, nitroprusside, or adenosine. Perforation occurs in approximately 1% of patients, typically when significant tortuosity forces the burr to the outside edge of a curve. Prophylactic pacing or aminophylline is frequently required if rotational atherectomy is performed in the vessel supplying the atrioventricular (AV) node. Rotational atherectomy is typically contraindicated in patients with thrombus, dissection, or severely reduced LV systolic dysfunction. GP IIb/IIIa inhibitors decrease the risk of CK-MB elevation.

H. Directional coronary atherectomy

1. John Simpson developed DCA in the 1980s in response to the high rate of balloon angioplasty complications. DCA uses a sharp blade that repeatedly shaves off eccentric plaque and requires an IVUS to ensure adequate debulking. This revascularization technique is effective in treating fibrotic, noncalcified, ostial, bifurcation, branch ostial, or bulky eccentric lesions in large proximal vessels (> 3 mm) and requires an experienced operator for safe and effective use.

   Despite multiple randomized prospective trials, optimal DCA has never been shown to have lower rates of TVR when compared with plain balloon angioplasty or stenting. As a result, DCA has little role in present-day interventional cardiology, although some cardiologists continue to use it for debulking bifurcation lesions and other eccentric, noncalcified, nonthrombotic lesions.

I. Excimer laser

1. The excimer (*excit*ed and di*mer*) laser catheter (excimer laser coronary atherectomy, ELCA) tip is brought into contact with the target lesion. It creates ultraviolet light (308 nm) at a rate of 25 to 40 pulses/s from a high-energy, metastable, dimeric molecule of xenon and chloride. This provides 45 mJ/mm^2, which can ablate 0.5 mm of tissue per second, and reduces the target tissue to gas and subcellular debris. The size of the lumen created is equivalent to that of the catheter (0.9 mm diameter).
2. The ELCA was approved by the FDA in 1992 for total occlusions, moderately calcified stenoses, balloon crossing/dilatation failures, ostial lesions, bypass grafts, and long diffuse disease. It is contraindicated in angulated lesions, coronary dissection, thrombotic lesions, and severely calcified lesions. However, long-term clinical data

have failed to demonstrate a significant restenosis benefit, and routine use increases the complication rate in comparison with plain balloon angioplasty. Therefore, the ACC/AHA PCI guidelines do not suggest use of ELCA as a primary strategy for revascularization and is used quite infrequently in the present day.

J. Thrombectomy

1. **Aspiration thrombectomy.** The use of a catheter to aspirate thrombus from the infarct artery is intuitively attractive and carries a class IIa indication in the ACC/AHA guideline management of STEMI. The Thrombus Aspiration during Percutaneous Coronary Intervention in Acute Myocardial Infarction Study (TAPAS) randomized 1,071 patients with STEMI to PCI with or without preparatory thrombus aspiration (TA) using the Export catheter. The primary end point of myocardial blush grade after intervention was higher with TA, along with less persistent ST-segment elevation, more ST-segment elevation resolution, and fewer pathological Q waves, along with a trend toward less death at 30 days ($p = 0.07$). Although clinical end points were not statistically different at 30 days, 1-year follow-up revealed significant reductions in all-cause mortality (4.7% vs. 7.6%, $p = 0.04$), cardiac death (3.6% vs. 6.7%, $p = 0.02$), and reinfarction (2.2% vs. 4.3%, $p = 0.05$) favoring TA. Similarly, a recent meta-analysis by Bavry and colleagues revealed a substantially lower mortality in patients assigned to receive aspiration thrombectomy (2.7% vs. 4.4%, $p = 0.018$) prior to PCI in STEMI. Currently, the most widely used aspiration catheters include the Pronto LP, Pronto V4, Export, and Extract (from smallest to largest lumen size; all these are compatible with a 6F system except the Extract which requires 7F).
2. **Rheolytic thrombectomy.** The Possis AngioJet is the dominant rheolytic thrombectomy device. The device is a 5F double-lumen, flexible catheter that contains a hypotube through which six high-speed saline jets create a low-pressure area at the tip (approximately –760 mm Hg), which serve to macerate and aspirate the thrombus back into the catheter lumen in accordance with the Venturi-Bernoulli principle. This catheter has proven to be successful in thrombotic vein grafts, for which it received FDA approval in 1998. Temporary prophylactic pacing is recommended when treating vessels supplying the inferior wall, because of temporary AV block. Temporary ST-segment elevation is frequent. Perforation can occur in vessels < 2.0 mm in diameter due to the high-pressure saline injection. Although small studies using the AngioJet in the setting of ACS have been encouraging, prospective randomized data demonstrating a clinical benefit have been lacking. The AngioJet Rheolytic Thrombectomy in Patients Undergoing Primary Angioplasty for Acute Myocardial Infarction (AiMI) trial randomized patients with acute MI to AngioJet thrombectomy followed by PCI or PCI alone and concluded that mortality rates (4.6% vs. 0.8%, $p < 0.02$), infarct size (12.5 ± 12.1% vs. 9.8 ± 10.9%, $p = 0.02$), and MACE rates (6.7% vs. 1.7%, $p < 0.01$) were considerably **higher** in those undergoing thrombectomy. While not used in the routine care of patients, the AngioJet still holds a place in the interventional armamentarium for patients with overwhelming clot burden that is not adequately addressed by aggressive aspiration thrombectomy alone.

K. PercuSurge GuardWire

1. Atheromatous embolization is a frequent and dreaded complication of degenerated saphenous vein graft (SVG) intervention. The first distal emboli protection device approved by the FDA was the PercuSurge GuardWire and Export catheter. The PercuSurge GuardWire is a 0.014" hypotube (i.e., hollow tube) with a balloon mounted on the distal end near the fixed floppy wire. The deflated balloon is steered across the SVG lesion and inflated in a distal portion of the graft. This results in cessation of blood flow in the SVG. Angioplasty and stenting are then performed, followed by removal of the column of blood with the Export catheter and then deflation of the occlusive balloon.

2. In the Saphenous vein graft Angioplasty Free of Emboli Randomized (SAFER) trial, the use of the PercuSurge GuardWire resulted in the recovery of atheromatous debris (83 to 204 μm) in 93% of cases and a 42% reduction in MACE (i.e., death or MI). There was also a lower incidence of periprocedural slow flow.
3. Randomized data have failed to demonstrate the benefit of using the PercuSurge GuardWire in the setting of STEMI. The Enhanced Myocardial Efficacy and Removal by Aspiration of Liberated Debris (EMERALD) trial found no benefit to using the PercuSurge GuardWire in regard to angiographically assessed myocardial reperfusion, ST-segment elevation resolution, or infarct size at 30 days.

L. Filters. Collapsible microporous polyurethane net attached to a nitinol ring anchored distally to a 0.014″ guidewire that can be advanced across high-risk SVG or carotid stenoses and then deployed downstream of the lesion. When deployed, these porous devices appear as a windsock or umbrella and allow blood to flow through while filtering any debris larger than 80 to 100 μm. Advantages are ease of use and avoidance of prolonged ischemia. Potential disadvantages are incomplete sealing, passage of smaller particles through the filter pores, overloading of the device, and spillage during device retrieval. The FilterWire EX Randomized Evaluation (FIRE) trial prospectively randomized 650 patients undergoing PCI of diseased SVGs to either the EPI FilterWire EX or the PercuSurge GuardWire embolic protection device and revealed equal efficacy of both types of devices in regard to the primary end point of death, periprocedural MI, or TLR at 30 days. This trial led to FDA approval of the FilterWire EX for use in degenerated SVGs.

XII. SVG INTERVENTIONS

A. Saphenous vein bypass grafts are frequently used in CABG surgery. However, 7% occlude the first week, 15% to 20% occlude the first year, and by the tenth year 50% of SVGs are occluded and 25% are severely degenerated. Redo CABG is high-risk surgery with high rates of morbidity and mortality that approach 7% to 10% nationally. At the Cleveland Clinic, the rate is 1.8%. A patient with a patent internal mammary artery graft to the LAD artery makes redo surgery less appealing. Patients with no arterial conduit, multiple failed SVGs, multivessel disease, and depressed LV systolic function are ideal candidates for redo surgery.

B. Early postoperative ischemia within the first 30 days usually reflects graft failure (often secondary to thrombosis) or incomplete revascularization, and urgent coronary angiography is indicated. Emergency PCI of the graft, even across suture lines, has been safely performed within days of surgery. Intracoronary thrombolysis should be used with caution. Mechanical thrombectomy is a safer choice. Given that SVG flow is pressure dependent, IABP use should be strongly considered in patients that present with hypotension or depressed LV function.

C. Recurrent ischemia 1 to 12 months after CABG surgery usually reflects perianastomotic graft stenosis. Distal anastomotic stenoses respond well to balloon inflation only. Midshaft vein graft stenoses are usually due to intimal hyperplasia.

D. Recurrent ischemia > 1 year after CABG surgery usually reflects the development of atherosclerosis. SVGs have greater plaque burden than native coronary arteries, and aspirates are composed of atherosclerotic rather than thrombotic elements. This may explain the lack of benefit seen with GP IIb/IIIa inhibitors. Unprotected PCI (i.e., no PercuSurge GuardWire or filter device) results in varying degrees of atheroembolization, with 15% of patients having a CK-MB more than five times normal. Therefore, use of distal protection devices during SVG interventions is strongly encouraged when technically feasible. The use of these devices is discussed above in Section **XI**. In situations of poor reflow after SVG PCI, copious administration of intracoronary adenosine and/or nitroprusside is recommended, with the goal of improving microvascular flow. It should also be noted that poor reflow may be seen due to a plaque-burdened filter, which should resolve with filter retrieval.

XIII. RESTENOSIS

A. Restenosis is the most commonly occurring late PTCA complication and typically occurs within 6 months due primarily to vessel contracture, elastic recoil, negative vessel remodeling, and neointimal hyperplasia. **ISR is almost entirely due to neointimal hyperplasia**. Not surprisingly, focal restenosis has a better outcome and response to treatment than does diffuse restenosis. **The predictors of restenosis include diabetes, unstable angina, acute MI, prior restenosis, small vessel diameter, total occlusion, long lesion length, SVG, proximal LAD artery, higher percent stenosis after the procedure, and smaller minimal luminal diameter after the procedure**. Strategies to decrease restenosis include maximizing stent expansion (i.e., bigger is better) and minimizing the distance of arterial injury.

B. Post-PTCA. Balloon angioplasty alone has a 6-month restenosis rate of 32% to 40%. For restenotic lesions managed with PTCA, the restenosis rate is comparable to de novo lesions. For a third episode of restenosis, PTCA has a restenosis rate approaching 50% (not 100%). With PTCA alone, late patency is 93% after three procedures. Only 1.6% of lesions require four or more procedures. Atheroablative approaches, such as excimer laser and rotational atherectomy, have not proven superior for managing restenosis. However, stents are superior to PTCA, with a 6-month TVR rate of 10% versus 32%.

C. In-stent restenosis. The risk of recurrent ISR after balloon angioplasty is 10% for focal ISR, 50% for diffuse restenosis, and 80% for total stent occlusion. Atheroablative approaches, such as use of the cutting balloon and rotational atherectomy, have not proven clinically superior to PTCA.

1. ISR occurs in 17% to 32% of patients treated with BMS depending upon such variables as vessel size, lesion length, diabetes mellitus, smaller postprocedure minimal luminal diameter, higher residual percent stenosis, and vessel location. In patients who cannot receive DES but for whom ISR is an issue, consideration may be given to a short course of oral sirolimus therapy. The Oral Rapamycin in ARgentina (ORAR studies I to III) investigators have found substantial reduction in TLR for BMS plus sirolimus (10 mg pre-PCI followed by 3 mg daily for 13 days) in comparison with BMS alone (8.3% vs. 38% at 1-year, $p < 0.001$) and equivalence in TLR compared with DES (8.2% vs. 7.0% at 18 months, $p = 0.84$) (1).
2. The observed rate of ISR is significantly lower with DES. As discussed previously, 5-year follow-up from the SIRIUS trial of Cypher SES yielded a 9.1% rate of TLR, similar to the 9.6% TLR rate at 5 years in the TAXUS IV trial of PES. Follow-up data for the EES (Xience V or Promus) have been published up to 2 years in SPIRIT IV and show an ischemia-driven TLR rate of 4.5%. The Intracoronary Stenting or Angioplasty for Restenosis Reduction—Drug-Eluting Stents for In-Stent Restenosis (ISAR-DESIRE) trial compared SES and PES with balloon angioplasty in 300 patients with ISR following BMS and demonstrated a significant reduction in restenosis at 6-month follow-up in the DES groups as compared with angioplasty alone (8% vs. 33%). A comparison of EES and PES revealed a significant improvement in recurrent TLR with EES (1% vs. 11.5%, $p = 0.0193$) at 1 year, but similar rates of MI, death, and ST. Atheroablative approaches, such as use of the cutting balloon and rotational atherectomy, have not proven clinically superior to PTCA.

D. Brachytherapy. Brachytherapy damages chromosomes and prevents cell division, thereby inhibiting neointimal hyperplasia. Both beta and gamma brachytherapy catheter-based systems use closed-end lumen catheters that deliver the source and keep it out of contact with the blood, allowing reuse. Both gamma (iridium 192) and beta (phosphorus 32 and strontium 90) brachytherapy result in approximately a 50% reduction in ISR compared with balloon angioplasty alone. It is important to ensure brachytherapy delivery to all balloon-injured segments in the target vessel, or else inadequate radiation to an injured segment can cause neointimal proliferation.

Brachytherapy can only be used once in each vessel, and long-term DAT with aspirin and clopidogrel is essential, given the risk of late in-stent thrombosis. Ultimately, long-term data are disappointing with a high failure rate; brachytherapy has therefore fallen largely out of favor.

XIV. PHARMACOLOGIC ADJUNCTIVE THERAPY

A. Antithrombins. Antithrombins prevent the generation of thrombin and/or inhibit the activity of thrombin. An antithrombin such as unfractionated heparin (UFH), bivalirudin (direct thrombin inhibitor, DTI), or enoxaparin (low-molecular-weight heparin, LMWH) should be used during all coronary interventions to prevent thrombus formation on the equipment. This principle applies even to patients with a high international normalized ratio (INR). The following provides a brief overview of the anticoagulant agents used during PCI. For specific data regarding their use during ACS, please refer to **Chapter 2**.

B. Unfractionated heparin

1. UFH binds and induces a conformational change in antithrombin, converting it to a more efficient inhibitor of circulating thrombin (factor IIa), factor Xa, factor IXa, factor XIIa, and kallikrein. The typical dose is 60 to 100 units/kg bolus if no GP IIb/IIIa inhibitor is given. If a GP IIb/IIIa inhibitor is given, then 50 to 70 units/kg of heparin is infused as a bolus. No maintenance infusion is given. UFH boluses are given to maintain an ACT of 250 to 300 seconds without concomitant GP IIb/IIIa inhibitor and closer to 200 seconds with GP IIb/IIIa inhibitors. Maintenance of appropriate levels of anticoagulation is imperative to safely navigate the path between thrombosis and bleeding complications.
2. In uncomplicated PCI cases, prolonged postprocedural heparin infusions increase bleeding complications and do not lower the likelihood of abrupt vessel closure or the rate of restenosis. The sheath should be removed when the ACT is < 180 seconds.

C. Low-molecular-weight heparin

1. LMWH results in more predictable factor Xa inhibition. LMWHs are increasingly being used in the setting of ACS, as a result of data suggesting a possible reduction in the combination of recurrent angina, MI, and death associated with the use of enoxaparin as compared with UFH (ESSENCE and TIMI IIb trials).
2. If a hospitalized patient has been given subcutaneous enoxaparin, a reasonable strategy is as follows. If PCI is performed within 8 hours of subcutaneous enoxaparin administration, then no additional heparin is required. If PCI is performed within 8 to 12 hours, an additional IV dose of 0.3 mg/kg of enoxaparin should be administered. If PCI is performed > 12 hours after enoxaparin injection, standard doses of UFH can be used.
3. When using LMWH, ACT measurement does not reflect the degree of anticoagulation and there is no rapid method for determining factor Xa activity. This inability to confirm adequate antithrombin activity and assess the level of anticoagulation with a bedside test makes some interventional cardiologists uncomfortable. Significant anti–factor Xa activity persists for about 12 hours. LMWH is only partially reversed with protamine.
4. Dosing LMWH in obese patients provides a much less reliable level of anticoagulation. Extreme caution should be exercised in patients with moderate-to-severe renal insufficiency (i.e., creatinine clearance < 30 mL/min), as the renal elimination of LMWH may result in unexpectedly high degrees of anticoagulation for a prolonged period. In these cases, most interventionalists will use an alternative antithrombotic agent.
5. Fondaparinux is a synthetic pentasaccharide that binds to antithrombin and induces a conformational change that increases its affinity for factor Xa. Fondaparinux has compared favorably with LMWH in both the NSTEMI and

STEMI settings, in large part due to a significant decrease in bleeding complications. However, there is an increased risk of guide-catheter thrombosis, which requires concomitant administration of UFH (OASIS-8).

D. Direct thrombin inhibitors (bivalirudin)

1. The initial DTI was isolated from leech saliva, although now these materials are synthesized using recombinant technology. These agents directly inhibit clot-bound thrombin without requiring an antithrombin cofactor. DTIs are better able to block both fluid-phase and clot-bound thrombin, which may be particularly important in a thrombus' platelet-rich environment.
2. A hirudin analog, bivalirudin, is becoming increasingly more common in catheterization laboratories and is an important anticoagulant for patients undergoing PCI. The REPLACE-2 trial compared bivalirudin with the combination of abciximab/UFH in a prospective, randomized, double-blind fashion and found it to be associated with fewer bleeding-associated complications and a statistically noninferior rate of MACEs. Bivalirudin has also shown similar salutary effects in patients with STEMI (HORIZONS-AMI) and NSTEACS (ACUITY). Please refer to **Chapter 2** for details of bivalirudin use in ACS.
3. Bivalirudin is given as a 1 mg/kg bolus followed by a 4-hour maintenance infusion of 2.5 mg/kg/h and by 0.2 mg/kg/h. A given bivalirudin dose provides a more predictable ACT than does UFH. The half-life is 25 minutes in patients with normal renal function, although in dialysis-dependent patients, the half-life may be as long as 3.5 hours. The maintenance infusion can be discontinued after completion of the coronary intervention. If a vascular closure device is not used, the sheath can typically be removed in 1 to 2 hours, given the drug's short half-life. Unfortunately, the effects of bivalirudin cannot be reversed.

E. Warfarin. Routine warfarin is no longer recommended unless a patient has a mechanical prosthetic valve, atrial fibrillation, or intracardiac thrombus. DAT has proven superior. An INR > 1.6 is a strong relative contraindication to elective cardiac catheterization. If emergent cardiac catheterization is required due to ACS or MI, consider accessing the radial artery because hemostasis is rarely an issue with this approach.

F. Antiplatelet therapy

1. Platelets are essential in thrombus formation, and some form of antiplatelet therapy is typically given at the time of PCI.
2. **Thromboxane A_2 inhibitor (aspirin).** Aspirin impairs platelet aggregation by irreversibly inhibiting platelet cyclooxygenase, thereby limiting thromboxane A_2 production. A loading dose of 325 mg of aspirin should ideally be given at least 2 hours before PCI and be continued at 325 mg daily for at least 1 month following the procedure. In the case of DES, higher-dose aspirin may be continued for longer periods. Secondary prevention trials have shown aspirin to reduce death, MI, and stroke by 27%. In PCI patients, aspirin reduces abrupt vessel closure.
3. **Adenosine diphosphate receptor antagonists (clopidogrel, ticlopidine, and prasugrel)**
   a. Thienopyridines such as clopidogrel and ticlopidine inhibit adenosine diphosphate–induced platelet aggregation by the $P2Y_{12}$ receptor. Clopidogrel is preferred to ticlopidine because of its better safety profile, although both require hepatic metabolism for activation.
   b. Ticlopidine is poorly tolerated with prolonged use, resulting in 20% of patients discontinuing the drug due to nausea, diarrhea, and rash. Neutropenia and thrombotic thrombocytopenic purpura (TTP) occur in 1% to 3% and 0.03% of patients, respectively. The complete blood count should be serially examined in the first several months of use (q2wk × 3 months).
   c. Clopidogrel is better tolerated than ticlopidine and has largely replaced it in clinical practice in the United States. The risk of TTP with clopidogrel is the

same as in the general population (11 in 3 million), and neutropenia is not an issue, making blood count monitoring unnecessary.

d. The ACC/AHA guidelines recommend routine clopidogrel pretreatment with a dose of 600 mg, although this recommendation is made on the basis of studies that included patients with ACS. In patients undergoing elective PCI, a recent study revealed no difference in ischemic or bleeding complications between 300 and 600 mg loading doses. Similarly, in patients on chronic clopidogrel therapy undergoing elective PCI, the ARMYDA-4 RELOAD investigators found no benefit to an additional 600 mg "reloading" dose of clopidogrel; the group of patients with NSTEACS did have a reduction in MACE at 30 days, however.

e. For a discussion of clopidogrel duration after PCI, please refer to Section **XI.D**. For details of clopidogrel use after ACS, please refer to **Chapter 2**.

f. The issue of clopidogrel nonresponsiveness, defined as platelet inhibition < 20%, is reported to be as high as 40% and is associated with worse clinical outcomes including ST, MI, and death. Mechanisms include genetic predisposition (i.e., CYP2C19 polymorphism that affects clopidogrel metabolism and thus activation) and drug–drug interactions (i.e., concomitant proton pump inhibitor use). Unfortunately, recent studies (including OASIS-7 and GRAVITAS) have not shown a benefit to higher maintenance dose clopidogrel (150 vs. 75 mg daily), even in patients with established high platelet reactivity while on clopidogrel. Management of these patients is therefore difficult, but we currently either use double-dose clopidogrel or change to prasugrel in cases of clopidogrel nonresponse.

g. Prasugrel is a novel thienopyridine prodrug that requires conversion to an active metabolite with high affinity for the platelet $P2Y_{12}$ receptor site, resulting in a potent antiplatelet effect. The TRITON-TIMI 38 trial randomized 13,608 patients with moderate-to-high risk ACS with scheduled PCI to either prasugrel or clopidogrel therapy and found a significant reduction in the primary efficacy end point of death from cardiovascular causes, nonfatal MI, or nonfatal stroke associated with prasugrel therapy. Prasugrel was also associated with a reduction in rates of MI, TVR, and ST. However, of some concern was a significant increase in major (HR 1.32, 95% CI 1.03 to 1.68, $p = 0.03$) and life-threatening (1.4% vs. 0.9%, $p = 0.01$) bleeding observed in the prasugrel group.

G. GP IIb/IIIa inhibitors (abciximab, eptifibatide, and tirofiban)

1. GP IIb/IIIa receptor inhibition prevents these receptors from binding to fibrin and forming the platelet–fibrin cross-linking that is required for thrombus formation. GP IIb/IIIa receptor occupancy > 80% prevents the development of thrombus.
2. **Abciximab** is a human–murine chimeric antibody fragment that binds the GP IIb/IIIa receptor with high affinity, resulting in a slow dissociation rate (i.e., noncompetitive inhibition). Although abciximab remains detectable on platelets for the lifetime of the platelet, it is rapidly cleared from plasma, allowing platelet aggregation to return to normal in 12 to 36 hours. Rapid reversal of platelet inhibition in the event of bleeding requires discontinuation of the abciximab infusion, waiting 30 minutes for plasma clearance, and platelet infusion (12 units) so as to provide functional platelets. Profound thrombocytopenia occurs in 0.4% to 1.1% of patients. Platelet counts should be measured within the first 2 to 4 hours and the following day. Abciximab readministration has not been associated with hypersensitivity or anaphylaxis, although the risk of profound thrombocytopenia is somewhat higher (2.2%).
3. **Eptifibatide** is a cyclic heptapeptide and **tirofiban** is a tyrosine derivative nonpeptide mimetic. Both act as competitive inhibitors requiring high levels for adequate inhibition. Both have a short plasma half-life (2.0 to 2.5 hours), with platelet aggregation normalizing in 30 minutes to 4 hours. In the event of bleeding, the infusion should be stopped. Unlike abciximab, the effect cannot

be reversed and platelets remain inhibited until plasma drug levels fall. Profound thrombocytopenia is rare (0.0% to 0.3%).

4. The use of GP IIb/IIIa inhibitors versus heparin alone during PCI prevents 65 adverse events per 1,000 treated patients and is arguably beneficial for all types of interventions. These benefits are particularly enhanced for unstable angina, diabetes mellitus, and bail-out stenting. Even in the contemporary era of stents and thienopyridines, a recent meta-analysis has demonstrated the reduction in nonfatal MI compared with heparin alone, although there was an increase in minor bleeding.
5. For specific recommendations regarding the use of GP IIb/IIIa inhibitors during ACS, please refer to **Chapter 2**.

H. Intracoronary vasodilators. PCI can result in no-reflow, which is defined as a reduction in coronary flow without an obstructive lesion. The most probable causes of no-reflow are microvascular spasm and distal embolization. Potent microvascular vasodilators, such as adenosine (36 to 72 μg), nicardipine (100 to 200 μg), nitroprusside (50 to 200 μg), or verapamil (200 μg), often restore normal flow. Nitroglycerin is a logical choice for relieving epicardial spasm but has no effect on the microvasculature. Immediately before SVG intervention, verapamil pretreatment has been shown to prevent no-reflow but has never been shown to reduce the risk of CK-MB elevation.

XV. SUPPORTIVE ADJUNCTIVE THERAPY

A. The use of percutaneous circulatory support during PCI may be necessary during high-risk intervention or in cases of acute MI presenting with cardiogenic shock. A number of devices exist for this application, although the data supporting their use are scant. Nevertheless, each of these may be appropriate on a case-by-case basis based on the physician judgment. This brief overview will address the use of percutaneous support for elective PCI.

B. Intraaortic balloon pump. There is usually a low threshold for prophylactic IABP insertion in high-risk PCI patients (e.g., poor ventricular function, large area of myocardial ischemia, critical left main trunk disease, and cardiogenic shock). While observational studies have suggested a benefit to this strategy, the only randomized trial comparing prophylactic IABP with bail-out IABP for high-risk PCI found no difference in MACE, MI, death, or hospital discharge. The bail-out group did have a higher rate of hypotension and 12% of patients required "rescue" IABP. Because of the inherent risk of complications, such as atheroembolism, distal limb ischemia, infection, and thrombocytopenia, IABP should be reserved for selected patients in whom there is an appropriate risk/benefit ratio.

C. TandemHeart (TH). The TH system is used for percutaneous LV support and consists of an inflow cannula placed from the femoral vein to the left atrium via transseptal puncture (21F) and an arterial outflow cannula placed in the femoral artery and parked in the descending aorta (15 to 17F). The device provides up to 5.0 L/min of cardiac output. Among 33 patients with cardiogenic shock, the majority of whom had undergone PCI for acute MI, randomized to IABP ($n = 14$) versus TH ($n = 19$), there was an improvement with TH with respect to cardiac output, pulmonary capillary wedge pressure, and mean arterial pressure. There was no difference in survival, but the number of patients was relatively small. These findings were subsequently corroborated by the ISAR SHOCK trial of TH versus IABP (increase in cardiac index 0.49 vs. 0.11 L/min/m^2 at 30 min, $p = 0.02$; 30-day mortality in both groups: 46%).

D. Impella 2.5 and 5.0. The Impella device is essentially a pigtail catheter that sits across the aortic valve and draws blood out of the left ventricle and ejects blood into the ascending aorta. The catheter comes in two forms: a 9F device (inserted via a 13F sheath) that supports an output of 2.5 L/min and a 9F system that supports an output of 5.0 L/min. The larger device requires a cut down at the femoral site for placement of the catheter because while the LV portion of the device has a 21F caliber, the shaft is only 9F (so the purse-string suture at the femoral site is cinched around the shaft once the device enters the artery). Registry studies have demonstrated the feasibility

of use of both devices. The PROTECT II randomized trial comparing high-risk PCI (defined as unprotected left main coronary or the last patent conduit and a left ventricular ejection fraction [LVEF] under 35% or three-vessel disease and an LVEF over 30%) supported by prophylactic placement of an Impella 2.5 versus IABP, however, was stopped early due to difficulty in enrolling patients. Of the patients enrolled, there were no significant differences in the two arms at 30 days. The investigators are quick to point out, however, that there were significant differences between the two groups of patients, as the Impella group more often underwent rotational atherectomy and were more likely to have a "complete revascularization" performed.

E. In contrast to the IABP, which requires at least modest LV function, the two percutaneous left ventricular assist devices (pLVAD; TandemHeart and Impella) can provide support to patients with minimal LV function. The pLVAD may thus be well suited to situations where an IABP has been ineffective, or in patients with hemodynamic catastrophe, as opposed to placement as a first-line means of support.

XVI. POST-PCI MANAGEMENT

A. Access site care

1. The groin or arm access site should be examined for hematoma, pseudoaneurysm (systolic bruit), and arteriovenous fistulas (continuous murmur). A pulsatile mass also suggests a pseudoaneurysm. Ultrasound studies can confirm the diagnosis of pseudoaneurysm or arteriovenous fistula. Suprainguinal tenderness, back pain, lower quadrant abdominal pain, or hypotension should make one suspicious for retroperitoneal hemorrhage, which can be confirmed by computed tomography (CT). A hemoglobin level 1 day after PCI should be routine, and a decrease > 2 g/dL is concerning. Distal pulses should be examined as well. Pulselessness, pain, pallor, paresthesias, and a cool extremity suggest an acute arterial occlusion.
2. **Pseudoaneurysms** < 2 cm often close spontaneously; those 2 to 3 cm can often be closed by external, ultrasound-guided compression (90% success rate); and those > 3 cm generally require surgical correction. Another frequently successful option is thrombin injection if the pseudoaneurysm has a thin neck.
3. **Arteriovenous fistulas** are typically small and inconsequential, rarely causing high-output failure. Indications for ultrasound-guided compression (success rate > 80%) or surgical closure include significant shunting, extremity swelling/tenderness, CHF, and deep venous thrombosis.
4. A **retroperitoneal hemorrhage** can be treated by supportive care (i.e., transfusions, close observation, and bed rest) in > 80% of cases. Anticoagulation must be reversed, and frequent hemodynamic monitoring in an experienced intensive care unit is required. If required, transportation to CT scan should be deferred until the patient is hemodynamically stable. If the bleeding does not spontaneously stop, the patient may require vascular surgery consultation. Other options include balloon tamponade or coil embolization if a small side branch is the culprit.
5. **Acute arterial occlusion** may be due to dissection or thromboembolism. Both typically require angiography of the affected extremity with access from another extremity (e.g., with a cold right leg after right femoral artery access, left femoral access should be obtained and an angiogram of the right lower extremity can be performed by crossing over to the right common iliac artery). Dissection typically requires prolonged balloon inflation and possible stenting or surgery. Stenting at the common femoral artery is discouraged, because it is a flexion point and a frequent site of attaching bypass grafts. Thromboembolism can be treated with surgical (Fogarty catheter) or percutaneous mechanical thrombectomy (Possis AngioJet).

B. Monitoring for myocardial ischemia. A 12-lead ECG should be obtained before and after PCI in order to have a baseline. The patient should be monitored on a cardiac ward that has continuous electrocardiographic monitoring and nurses familiar with routine post-PCI care. The creatine kinase (CK) and CK-MB levels should be measured 12 hours after the intervention. A procedural MI is presently

defined as a CK-MB more than three times the normal (assuming a normal baseline CK-MB). Elevated CK, CK-MB, or electrocardiographic abnormalities occur in 5% to 30% of patients. Mechanisms include distal embolization, side branch occlusion, dissection, and spasm. Troponin levels are not routinely measured after PCI.

C. Monitoring for contrast-induced nephropathy. Nonsteroidal anti-inflammatory drugs, cyclosporine, and metformin should be withheld for 24 to 48 hours beforehand and for 48 hours afterward. Postprocedure saline hydration is continued at 75 to 150 mL/h for a total infusion of 1 to 2 L. Renal function (serum creatinine) should be monitored in patients with diabetes and renal dysfunction.

Percutaneous Structural Heart Disease Procedures

The last decade witnessed a remarkable rise in the number of novel percutaneous, catheter-based procedures using new concepts and technologies for the treatment of structural heart disease. Most percutaneous therapies have largely evolved from concepts developed by surgeons and often incorporate the lessons learned from established surgical procedures. Currently, percutaneous catheter-based therapy is available for a number of valvular disorders, including aortic stenosis (AS), mitral stenosis (MS), mitral regurgitation (MR), and prosthetic paravalvular leaks (PVLs), as well as other structural cardiac disorders such as hypertrophic obstructive cardiomyopathy (HOCM), patent foramen ovale (PFO), and atrial septal defects (ASDs). While a comprehensive review of structural cardiac interventions is beyond the scope of this chapter, we provide an overview of the major devices and clinical studies that have been performed.

I. PERCUTANEOUS TRANSCATHETER MITRAL VALVE REPAIR (MVRE)

A. Background. MR is one of the most common valvular disorders, encountered in about 7% of the population aged > 75 years. MVRe, when feasible, produces superior outcomes, including lower operative mortality, improved long-term survival, and reduced incidence of endocarditis and thromboembolic complications, compared with mitral valve replacement (MVR). A number of percutaneous MVRe techniques have been developed that are analogous to surgical procedures. Percutaneous mitral annuloplasty leverages the close relationship of the coronary sinus (CS) to the posterior mitral annulus. The **Carillon** (Cardiac Dimensions, Kirkland, WA) device, which has been granted Conformité Européenne (CE Mark) approval, is deployed in the CS and serves to "cinch" the annulus, resulting in improved mitral valve (MV) leaflet coaptation. There are also numerous other devices in various stages of preclinical and clinical development.

The **MitraClip** (Abbott Vascular, Santa Clara, CA) remains the most widely tested system in humans and is currently the only device available (under trial basis) in the United States. A total of more than 4,000 procedures have been performed in the United States (under trial) and Europe (where the device has CE Mark approval). The technique is based loosely on the surgical Alfieri stitch, which brings the anterior and posterior leaflets in close apposition using a suture and creates an anatomic "double-orifice" MV.

B. Procedure. The MitraClip system uses a steerable 22F guide catheter that is introduced through the femoral vein and subsequently advanced to the left atrium via transseptal puncture (Fig. 66.1). Through this guiding catheter, a delivery system containing the V-shaped clip is introduced in the left atrium and positioned with the arms of the clip perpendicular to the MV line of coaptation using transesophageal echocardiography (TEE) guidance. The clip is advanced to the left ventricle in an open position and retracted to grasp the anterior and posterior MV leaflets at the desired location. After confirmation by TEE of clip position, the clip can be locked.

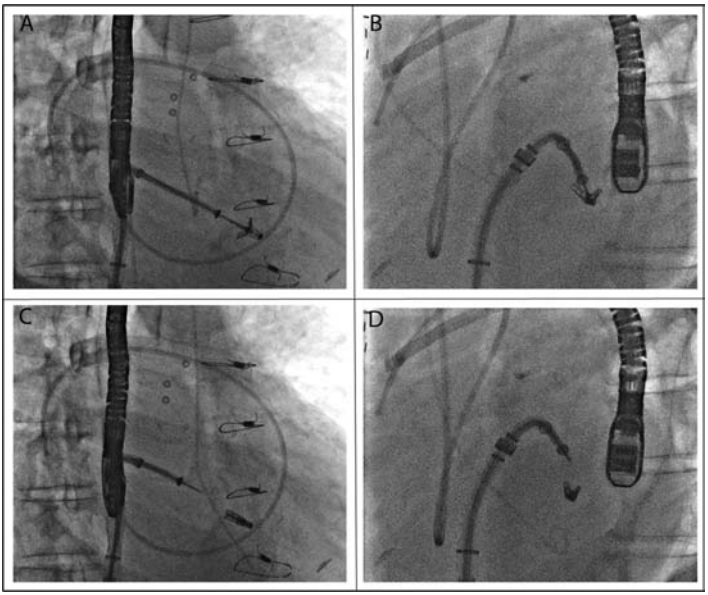

FIGURE 66.1 Percutaneous transcatheter mitral valve repair. Panel A demonstrates the right anterior oblique projection of the optimal positioning of the MitraClip device. Panel B demonstrates the left anterior oblique projection of the optimal positioning of the MitraClip device. Panel C demonstrates the right anterior oblique projection of MitraClip after its release from the delivery catheter. Panel D demonstrates the left anterior oblique projection of MitraClip after its release from the delivery catheter.

If satisfactory (by TEE), the clip can be released; otherwise, it can be reopened and the process repeated. If necessary, multiple clips can be deployed to achieve a satisfactory result. Care must be taken in this situation to not impede forward flow across the valve and trade MR for MS.

C. Complications. Routine complications associated with vascular access like major or minor bleeding are the most commonly encountered complications. Recurrent MR and the requirement for MV surgery are the prime limitations of the current technique, especially in ischemic MR or in the presence of a significant annular calcification. Partial clip detachment is the most important mechanical problem encountered with the procedure. These are generally not symptomatic and are treatable with MV surgery or placement of an additional clip. Iatrogenic MS is a significant complication that may arise as a result of this procedure. Careful echocardiographic evaluation of the MV apparatus is important prior to leaflet plication. A coaptation length of at least 2 mm, a baseline MV area of at least 4 cm^2, and central origin of the regurgitant jet should be ensured prior to the percutaneous repair, to maximize success and avoid complications.

D. Outcomes. The edge-to-edge repair technique was tested in the EVEREST I (Endovascular Valve Edge-to-Edge REpair Study) safety and feasibility trial, which demonstrated a 74% procedural success rate (reduction in MR to ≤ 2+) with a < 1% inpatient mortality rate. Freedom from death, MV surgery, or MR > 2+ was 66% at the end of 1 year. Data from the pivotal EVEREST II trial, which randomized 279 patients to MitraClip versus surgical repair in a 2:1 fashion, demonstrated freedom from the combined end point (death, MV surgery within 90 days, or MR > 2+ at

1 year) of 72.4% and 87.8% in the two groups, respectively, confirming noninferiority of the MitraClip to conventional surgical treatment.

The initial studies of the MitraClip concentrated on patients with degenerative disease. However, the EVEREST II trial and the clinical experience in Europe (where the device enjoys the CE Mark) have shown efficacy in a large number of patients with functional MR as well. Freedom from significant MR was enjoyed by more than 80% of high surgical risk patients, with resultant decreases in left ventricular (LV) volume, NYHA class, congestive heart failure (CHF) hospitalizations, and improved quality of life. Percutaneous MVRe procedures still remain investigational in the United States and in the current iterations available are applicable to patients in whom surgery is of relatively high risk, given the excellent outcomes with surgical MVRe in terms of both freedom from reoperation and significant MR and operative morbidity and mortality.

II. PERCUTANEOUS MITRAL BALLOON VALVULOPLASTY (PMBV)

A. Background. Although there has been a significant reduction in the prevalence of rheumatic heart disease in western countries, it still represents a major public health concern in the developing world. MS is one of the most common presentations of rheumatic heart disease. It continues to represent a major clinical problem in the United States primarily due to outmigration from developing countries or the occurrence of restenosis after previous surgical commissurotomy. Stenosis of the valve may occur due to commissural fusion, leaflet thickening, and/or chordal shortening and fusion.

Before the advent of PMBV, symptomatic MS was treated using surgical commissurotomy. Since the introduction of the percutaneous procedure in the early 1980s by Inoue and colleagues, PBMV has evolved to become the first line of therapy for appropriately selected patients with MS. The technique works similarly to commissurotomy, resulting in opening of the fused commissures.

B. Procedure. The Wilkins splitability score is the most widely used echocardiographic parameter to determine the safety and feasibility of PBMV, and this takes into consideration leaflet mobility, leaflet thickening, subvalvular thickening, and valve calcification (each scored 1 to 4 points). Multiple investigators have shown that patients with a score of 8 or less have the greatest freedom from death and valve surgery and the largest improvement in mitral valve area with PMBV.

Selection of the appropriate balloon size is one of the most important steps for accomplishment of a successful PBMV. A good rule of thumb is to use the following formula to determine the maximum balloon dilation size: Balloon size (mm) = patient height (cm)/10 + 10 mm. Sizing of the balloon with contrast inflation is confirmed ex vivo using a measurement device (provided). We routinely perform the procedure as follows: a 5F arterial access is obtained in order to obtain left ventriculography to understand the position of the MV and commissural anatomy in the fluoroscopic projection. Transseptal puncture is performed (most commonly with TEE guidance) using the standard Brockenbrough needle via a 9F Mullins sheath placed in the femoral vein. Once the sheath has entered the left atrium, it is exchanged for the Inoue balloon catheter.

The balloon catheter is slowly advanced into position in the left ventricle. The Inoue balloon consists of three portions with slightly different compliances. As pressure is added to the balloon, the distal portion inflates first followed by the proximal portion. As soon as the distal portion is inflated, the balloon is pulled until resistance is felt. On addition of more pressure, the proximal portion is inflated, which fixes the valve in the middle waist portion of the valve. The middle waist has the least compliance and dilates only when substantial pressure is added to the balloon, thereby securing the balloon across the valve prior to the dilation of the annulus.

In our institution, we routinely use TEE to guide the valvuloplasty in order to assess the result of balloon inflation (in addition to simultaneous left atrial [LA]–LV

gradient measurement) and, more importantly, to evaluate the degree of MR. Substantial increases in MR should preclude further inflation. In addition, the procedure should be aborted in the presence of left atrial appendage (LAA) clot. Some institutions have gained facility in using intracardiac echocardiography (ICE) in this application.

C. Complications. The most common serious complications include hemopericardium or severe MR. Perforation of cardiac chambers, which occurs with a rate of 0% to 2%, may happen while manipulating the catheters in the heart. While an increase in MR may routinely be noted after the PMBV, it rarely requires a surgical intervention.

D. Outcomes. Immediate postprocedural success with a final valve area > 1.5 cm^2 without moderate or severe MR is the best predictor of long-term outcome. The best results are obtained in young people with favorable anatomic characteristics. Randomized clinical trials have demonstrated that long-term results of PMBV in young patients are as good as open commissurotomy and are better than closed commissurotomy. In patients with optimal morphology, freedom from restenosis has been reported as 92% at 5 years, 85% at 10 years, and 65% at 15 years. Repeat PMBV has been recommended as first-line therapy in patients with symptomatic mitral restenosis after PMBV or commissurotomy in whom the mechanism of restenosis is commissural fusion.

III. BALLOON AORTIC VALVULOPLASTY (BAV)

A. Background. Degenerative or calcific AS is one of the most common valvular disorders encountered in western countries. Surgical aortic valve replacement (SAVR) is the treatment of choice for patients who are safely able to undergo cardiac surgery, and transcatheter aortic valve replacement (TAVR) is emerging as a favorable option in patients at high risk for surgical complications. Balloon dilation of the calcified aortic valve results in stretching of the fused commissures. Due to rapid reversibility of these effects, there is an early loss of effectiveness in severe degenerative AS, and the valve returns to pre-BAV size in 3 to 6 months.

In patients with severe AS who are hemodynamically unstable and for whom urgent aortic valve replacement (AVR) is not feasible, BAV may serve as a "bridge" to valve replacement. Similarly, we have also seen significant functional improvement in patients after BAV so that patients unable to undergo AVR initially have improved to a point that TAVR or SAVR could be performed safely. In patients who require urgent noncardiac surgery, BAV may be considered as a temporizing measure in the hope of reducing the risks of perioperative hemodynamic changes associated with anesthesia.

A number of patients with severe AS have other comorbidities, such as chronic obstructive pulmonary disease or liver or kidney disease, that make it difficult to discern the degree to which AS contributes to their symptoms. In such cases, BAV may provide a therapeutic answer; improvement of symptoms points to AS as the driver of symptoms and may push for a more definitive valve replacement option. Finally, in patients without any option for either TAVR or SAVR, BAV may be considered as a palliative measure.

B. Procedure. The femoral retrograde approach is the most commonly utilized method for BAV, although in patients with severe iliofemoral disease the procedure can be performed in an antegrade fashion via venous access and transseptal puncture. A Swan-Ganz catheter is placed in the pulmonary artery for continuous hemodynamic monitoring and assessment of cardiac output. A temporary pacemaker is placed in the right ventricle to perform rapid pacing (180 beats per minute) during balloon inflation to reduce cardiac output and minimize balloon movement in the annulus. After crossing the aortic valve using a 5F AL-1 diagnostic catheter and a straight wire, a stiffer wire is inserted and positioned in the left ventricle. BAV is typically performed using balloons ranging from 15 to 25 mm in diameter. The balloon is sized based on the annulus diameter on transthoracic echocardiography

(TTE); the maximum balloon size is 10% larger than the annulus, and we routinely begin dilation at smaller sizes and assess the hemodynamic result prior to increasing the balloon size. Procedural success with BAV is typically defined as a 50% reduction in mean aortic valve gradient and a 25% increase in aortic valve area (AVA); most patients usually experience almost a 50% increase in AVA.

C. Complications. It should be noted that BAV carries considerable risk. The 30-day mortality associated with the procedure may be up to 10%, usually due to either aortic regurgitation (as a complication of the balloon procedure) or persistent heart failure. Other complications (occurring in up to 15%) include stroke, peripheral vascular complications (due to the size of the devices used and concomitant incidence of peripheral arterial disease), coronary occlusion, need for permanent pacemaker implantation, cardiac tamponade, and cardiac arrest.

D. Outcomes. Despite a modest improvement in valve area, a significant improvement in the functional status is noted after BAV. However, the benefit of BAV gradually disappears over the course of the next few months. The poor functional status of the patients, as well as only moderate, transient effects of the technique, is primarily responsible for the overall grim long-term results of stand-alone BAV. Although there are no contemporary studies comparing SAVR with BAV, extensive data indicate that stand-alone BAV does not change the natural course of AS, even after repeated procedures. Despite this, BAV holds an important place in the treatment of patients with severe AS. In our current experience, BAV is most often performed to bridge severely symptomatic patients to TAVR or SAVR or to better understand the contribution of AS to functional limitation in patients with multiple comorbidities. BAV has tremendous potential to alleviate symptoms and provide an opportunity for functional improvement that allows definitive treatment with AVR and improved quality and quantity of life in patients with severe AS.

IV. TRANSCATHETER AORTIC VALVE REPLACEMENT

A. Background. Up to a third of patients with severe symptomatic AS do not undergo surgical AVR, as they are deemed to have a high surgical risk due to age or multiple comorbidities. The interest in percutaneous aortic valve implantation began in the early 1990s. The first human experience was reported by Cribier et al. in 2002. Since then, rapid advancements in the design of the stented valve and delivery catheters and improved facility in implantation techniques have led to a consistent improvement in the postprocedural outcomes and have heralded a new era in the treatment of valvular AS.

The procedure involves implantation of a tissue pericardial valve that is mounted within a stent. The key to TAVR success is a careful selection of patient population for the procedure and a judicious use of preprocedural and intraprocedural imaging modalities, including fluoroscopy and aortic angiography.

Currently, the indications for TAVR include severe symptomatic AS with a valve area of ≤ 0.8 cm^2, mean aortic valve gradient of ≥ 40 mm Hg, or a peak aortic jet velocity of ≥ 4.0 m/s with one or more of the following:

(1) High risk for conventional AVR (Society of Thoracic Surgeons score > 10 or logistic EuroSCORE > 20%) (web site 209.220.160.181/STSWebRiskCalc/).

(2) Contraindication to standard thoracotomy including prior multiple thoracotomies or radiation to the chest wall.

(3) Porcelain aorta.

B. Procedure. Two types of stented valves have been tested in humans: the balloon-expandable Edwards SAPIEN valve (Edwards Lifesciences, Irvine, CA) and the self-expanding CoreValve ReValving system (Medtronic Inc., Minneapolis, MN) (Fig. 66.2).

1. Edwards SAPIEN. The largest human experience is with the Edwards Lifesciences series of balloon-expandable aortic valves. The valve consists of a tubular

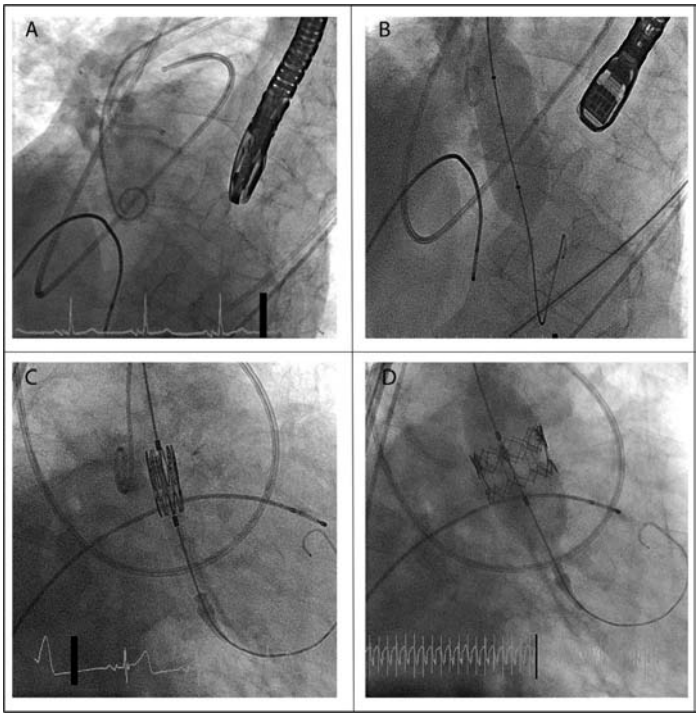

FIGURE 66.2 Transcatheter aortic valve replacement. Panel A demonstrates proper positioning of various catheters and devices for valve replacement: a transesophageal echocardiography probe in the esophagus, a Swan-Ganz catheter in the pulmonary artery, a pigtail catheter in the aortic root, AL-1 diagnostic catheter in the ascending aorta (prior to valve crossing), and a temporary pacemaker wire in the right ventricle. Panel B demonstrates aortic valvuloplasty being performed using a standard balloon. Panel C demonstrates proper positioning of the crimped Edwards SAPIEN prosthesis across the aortic valve. Panel D demonstrates the deployment of the valve using balloon inflation after initiation of rapid pacing.

stainless steel stent with a fabric valve cuff and contains valve leaflets derived from bovine pericardial tissue. This valve is available in two sizes, 23 mm (via 22F sheath access) and 26 mm (via 24F sheath access), and refers to the fully expanded internal stent diameter. Generally, a 23 mm valve is implanted in annuli that measure 18 to 22 mm, and a 26 mm valve is implanted in annuli that measure 23 to 26 mm. Although the valve was implanted initially using the transvenous access and subsequent transseptal puncture, it is now routinely implanted using either a retrograde transfemoral approach or an antegrade transapical approach. Furthermore, the newest iteration of the valve, the SAPIEN XT, which consists of a cobalt chromium stent and allows a smaller sheath size for insertion (18F for 23 mm valve and 19F for 26 mm valve), is currently in use in the Placement of Aortic Transcatheter Valves (PARTNER) II study.

The preprocedural assessment consists of TTE, iliofemoral contrast angiography or iliofemoral computed tomography, and coronary angiography. An iliofemoral diameter of at least 8 mm is required for implantation of the larger Sapien valve,

7 mm for the smaller Sapien valve, and 6 mm for the Sapien XT or CoreValve devices. Appropriate patient selection, which includes the anatomic characteristics of the aortic annulus and iliofemoral system, is imperative to procedural success.

a. **Transfemoral TAVR.** Transfemoral TAVR is usually performed under general anesthesia in a catheterization laboratory or hybrid operating room equipped with multimodality imaging equipment. Vascular sheaths are placed in a standard fashion in both femoral arteries and veins. Establishing early contralateral arterial and venous access is useful in case of ileofemoral trauma requiring emergency crossover endovascular repair or in case of the need to emergently establish a cardiopulmonary bypass circuit. A transvenous pacing wire is introduced into the right ventricle through the venous access port to enable rapid pacing (180 beats per minute) in order to minimize cardiac output and valve movement during valve deployment. An aortic angiogram is performed to delineate the aortic root anatomy and to facilitate optimal valve positioning. A BAV is then performed using standard technique, with a balloon that is slightly smaller than the size of the planned valve prosthesis.

   After routine sheath placement, the femoral access site is "preclosed" using either a Prostar device or two perpendicularly placed Perclose ProGlide devices (Abbott Vascular, Santa Clara, CA). The site is then sequentially dilated to allow placement of either a 22F (for 23 mm valve) or a 24F (for 26 mm valve) arterial sheath. The valve is crimped onto a balloon affixed to a steerable guiding catheter and advanced to the aortic root under fluoroscopic guidance. Once a suitable position is confirmed using fluoroscopy, aortic angiography, and TEE, rapid pacing is initiated and the valve is deployed by inflating the balloon. The final positions of deployment as well as degree of paravalvular aortic regurgitation are assessed using TEE.

   Inappropriate positioning may require a second valve deployment. Excessive paravalvular aortic regurgitation may be treated using further balloon dilation or deployment of a second valve. TEE and angiographic assessment for complications (including pericardial effusion, aortic root trauma, and coronary occlusion by the valve) are imperative prior to closure of the femoral access. Similarly, angiography of the iliofemoral system is necessary to evaluate for vascular trauma that might require endovascular or open surgical repair prior to completion of the procedure.

b. **Transapical TAVR.** Transapical TAVR is indicated in patients with significant narrowing of iliofemoral vessels and who otherwise meet criteria for TAVR. Preprocedural imaging as well as the valve sizing is similar to the transfemoral TAVR described above. After induction of general anesthesia, a 5 to 8 cm anterolateral thoracotomy incision is made to enter the pleural space, directly overlying the apex. The pericardium overlying the apex is opened and a thin portion of the ventricular apex is identified using palpation and TEE. Paired orthogonal U-shaped sutures are placed into the ventricular myocardium and subsequently passed through tensioning tourniquets. Taking due precaution to avoid entry of air into the left ventricle, a 7F sheath is placed into the LV cavity through the apex. A stiff wire is introduced into the sheath, passed across the aortic valve, and positioned into the descending aorta. Femoral access is utilized to place a pigtail catheter into the ascending aorta for aortic root angiography as required. The 7F sheath is upsized to a 14F sheath and aortic valvuloplasty is performed. Subsequently, the 14F sheath is exchanged for a 24F sheath. The mechanically crimped prosthesis is subsequently introduced using a balloon-tipped steerable catheter through this larger sheath and positioned across the aortic valve. After confirmation of optimal positioning using multimodality imaging, rapid pacing is initiated, and the valve is deployed by balloon inflation.

The sheath is then removed and hemostasis is secured with the previously placed sutures. Subsequently, the pericardium is approximated, drainage tubes are placed, and the chest incision is closed.

2. **CoreValve ReValving system.** The CoreValve system is a self-expanding porcine prosthesis mounted within a nitinol frame and is available in two sizes: 26 mm (intended for annuli 20 to 23 mm) and 29 mm (intended for aortic annuli 24 to 27 mm). The current third-generation device is delivered through an 18F system, commonly via transfemoral and rarely via trans-subclavian or transapical approaches. The general principles involved in the implantation of the valve are similar to balloon-expandable stent implantation. One specific difference in the two devices is that the CoreValve can be repositioned if initial placement is unsatisfactory.

C. Complications. Procedural success has ranged from 86% to 100% across the literature. After an initial learning curve, excellent procedural success rates with minimal intraprocedural mortality have been reported at major tertiary care centers performing TAVR. Vascular access complications are encountered more often (16% to 18% patients) than with other interventional procedures due to the large sheath sizes used for TAVR. Complications associated with limited thoracotomy are expected after transapical TAVR. Malposition of the aortic prosthesis may be encountered in about 1% to 3% of cases. Periprocedural strokes have been reported in 4% to 7% of patients undergoing TAVR with an Edwards SAPIEN valve and about 3% with the CoreValve prosthesis. Major complications following CoreValve implantation include the need for permanent pacemaker implantation in up to one-third of patients.

D. Outcomes. The PARTNER trial was the first multicenter randomized controlled trial of TAVR and provided two important randomized comparisons. Cohort B compared the outcomes in 358 patients with severe symptomatic AS who were unsuitable for surgery and were randomized to standard therapy including BAV versus TAVR with the Edwards SAPIEN valve. All-cause mortality at the end of 1 year was 30.7% in the TAVR group versus 50.7% with standard therapy ($p < 0.001$). Cohort A compared the outcomes in 699 high-risk AS patients randomized to TAVR versus surgical AVR. There were no significant differences in 30-day or 1-year mortality between the two groups; however, there were important differences in periprocedural complications. The TAVR group encountered a higher rate of stroke and vascular complications, and the surgical AVR group encountered a higher rate of atrial fibrillation (AF) and major bleeding.

Several prospective studies reported similar benefits using the CoreValve prosthesis. A large prospective registry of 663 patients undergoing TAVR with the third-generation CoreValve reported procedural success of 98%, with intraprocedural mortality of 0.9%. The cumulative incidence of mortality was 5.4% at 30 days and 15.0% at 1 year. Major complications after CoreValve implantation included postprocedural PVL (21%) and the need for a permanent pacemaker (10% to 33%).

Based on the encouraging results of PARTNER Cohort B, the Edwards SAPIEN valve was recently granted US FDA approval for use in inoperable patients. The CoreValve is still available for use in the United States only under the auspices of a clinical trial. Both valve systems have been granted CE Mark approval. A number of other valve systems are currently in various phases of preclinical and clinical development.

V. PFO CLOSURE

A. Background. PFO is a remnant of fetal cardiac circulation and is found in 27% to 33% of adults. Although generally believed to be an "innocent bystander," PFO has been associated with stroke, migraines, platypnea-orthodeoxia, and decompression sickness among divers. PFO arises when the septum primum and septum secundum fail to fuse despite some degree of overlap. Atrial septal aneurysms and prominent Chiari networks have been associated with PFO. Percutaneous PFO closure is currently recommended in patients with platypnea-orthodeoxia and in divers with decompression sickness. Although several observational studies have shown the

benefits of PFO closure in the prevention of migraine and cryptogenic strokes, these findings have not been confirmed in major randomized trials. Hence, controversy persists regarding definitive indications and settings for PFO closure for migraine and cryptogenic stroke prevention.

All PFO closure devices have a similar design, usually consisting of two atrial disks connected by a short neck. Under fluoroscopic and ICE guidance, the device is placed such that the two atrial disks lie on either side of the interatrial septum, with the neck positioned in the PFO tunnel. A large part of the atrial shunt is eliminated as a result of physical obstruction to flow. Most of the residual shunt is eliminated over the course of a few months after the procedure, as the device becomes endothelialized. Dual-antiplatelet therapy is generally recommended for the first 6 months after closure to minimize the risk of thromboembolism prior to device endothelialization.

B. Procedure. Several devices for transcatheter PFO closure have been tested in humans, including the Helex septal occluder device (WL Gore & Associates, Newark, DE) and the Amplatzer cribriform ASD occluder device (AGA Medical, Golden Valley, MN) (Fig. 66.3). As these devices are FDA approved only for ASD closure, use for PFO closure is "off-label." Sizing of the devices may vary based on the degree of associated atrial septal aneurysm; significant aneurysm generally requires a larger device.

Briefly, the procedure involves placement of an 8F to 12F vascular sheath (depending on device size) in one femoral vein and a 9F sheath in the contralateral femoral vein

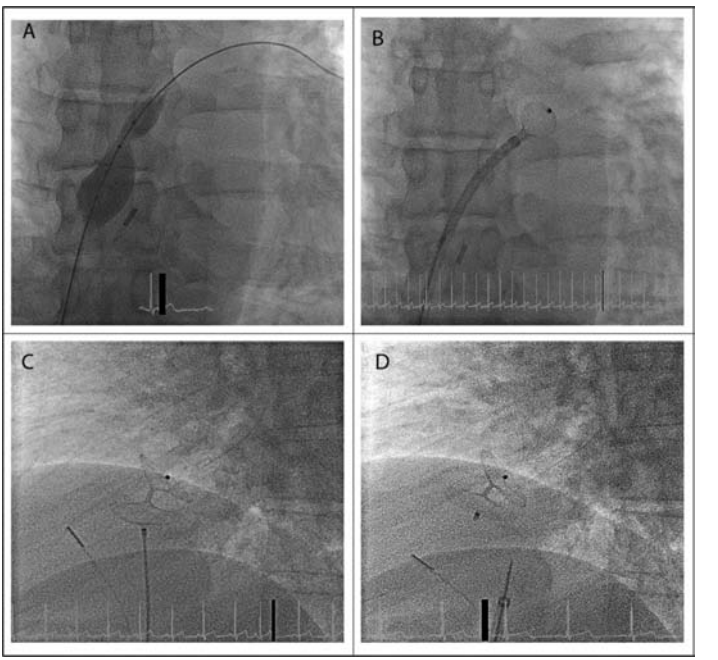

FIGURE 66.3 Patent foramen ovale closure using Amplatzer device. Panel A demonstrates balloon sizing of the PFO tunnel after crossing the PFO using a wire. The intracardiac echocardiography probe is visible next to the balloon. Panel B demonstrates deployment of the left atrial disk of the Amplatzer occluder device. Panel C demonstrates the deployment of the right atrial disk of the Amplatzer occluder device. Panel D demonstrates the device in place after its release from the delivery catheter.

for ICE. The ICE catheter is parked in the right atrium for procedural visualization. The PFO is usually crossed using a wire and a Goodale-Lubin (GL) catheter under ICE and fluoroscopic guidance. Through the GL catheter parked in the left superior pulmonary vein, the wire is exchanged for a stiffer wire over which the closure device delivery system is advanced. The LA disk of the device is deployed and the system slowly retracted. This action facilitates apposition of the septum primum to the septum secundum and effectively closes the PFO. The right atrial disk is then deployed. After confirmation of positioning and stability using ICE and fluoroscopy (and sometimes right atrial angiography), the device is released from the delivery catheter.

C. Complications. Transcatheter PFO closure is generally associated with a high procedural success rate and without significant risk of complication. Rare complications including device migration or embolization, symptomatic air embolism, and AF or chamber perforation with cardiac tamponade may occur intraprocedurally. Later complications associated with the procedure include thrombus formation (more common with CardioSEAL than Amplatzer), device erosion, or formation of a new ASD.

D. Outcomes. Several large observational studies have demonstrated benefit of PFO closure in secondary prevention of migraine and prevention of recurrent neurological thromboembolism in patients with cryptogenic stroke or transient ischemic attack (TIA). However, these findings have not been ratified in randomized clinical trials. The Migraine Intervention with StarFlex Technology (MIST) study failed to demonstrate any significant difference in migraine cessation between the closure and the "sham" arms. The preliminary results of the randomized controlled trial (CLOSURE I) comparing transcatheter PFO closure with the StarFlex device and optimal medical therapy in patients with cryptogenic thromboembolism failed to demonstrate any significant difference in the rate of recurrent stroke or TIA at the end of 2 years of follow-up in the transcatheter closure group (5.9%) and medical therapy (7.7%) ($p = 0.3$). It has been argued that the inclusion criteria may have been too liberal, however, and therefore could not show a significant difference between the two groups. Furthermore, the procedure was performed using the StarFlex device, which has since been taken off the market due to poor performance and increased risk of adverse events such as thrombus formation. Percutaneous closure of PFO is reasonable in certain clinical scenarios, and a thorough workup is necessary for appropriate patient selection.

VI. ASD CLOSURE

A. Background. ASD is one of the most common adult congenital heart diseases encountered in the US population. Although ASDs generally remain asymptomatic till early adulthood, they are associated with several clinical presentations, including right ventricular failure, atrial arrhythmias, pulmonary hypertension, and paradoxical embolism.

Patients with hemodynamically significant ASD should undergo elective closure either surgically or with the transcatheter technique. The hemodynamic significance of an ASD is determined by the presence of right ventricular enlargement in the presence of defect diameter > 1 cm or the presence of significant left-to-right shunting with an elevated shunt ratio (Q_p:Q_s > 1.5).

The principle of ASD closure is similar to that of PFO closure, entailing implantation of an occlusion device with atrial disks lying on either side of the interatrial septum and the central waist residing in the ASD. Due to significant variations in size and anatomy of ASD, transcatheter ASD closure is technically more challenging than PFO closure.

B. Procedure. Several devices have been used for percutaneous ASD closure. The Amplatzer atrial septal occluder (AGA Medical, Golden Valley, MN) has the largest reported human experience. The other major device available is the Helex (WL Gore & Associates, Newark, DE). The CardioSEAL and StarFlex occlusion devices (NMT Medical, Boston, MA) have been removed from the market due to adverse events.

The procedural approach to percutaneous ASD closure is similar to the percutaneous PFO closure approach as described above. A few important differences exist that are worth considering.

1. Due to a significant variation in the size of ASD and the shape of the defect, proper invasive balloon sizing (by ICE and fluoroscopy) is needed. Both oversizing and undersizing of the device may be hazardous and may lead to complications like device erosion or device embolization.
2. Device deployment and orientation during transcatheter ASD closure poses greater technical challenges than during PFO closure. The technical complexities are more frequent when ASDs are associated with other structural anomalies like atrial septal aneurysms or in cases of inadequate rim capture. It is imperative to demonstrate an adequate rim surrounding the defect for percutaneous closure.
3. Multiperforated septa demonstrate a particularly greater challenge to complete closure. In these cases, specific devices like the Amplatzer cribriform occluder or multiple devices may be needed to achieve a good clinical result.
4. The Amplatzer device is sized based on the defect size (i.e., 16 mm device for a 16 mm ASD) and can be used to close defects 2 to 38 mm in diameter. The Helex device is sized two times the size of the defect (i.e., 30 mm device for a 15 mm ASD) and can be used to close defects 2 to 17 mm in diameter.

C. Complications. As in transcatheter PFO closure, procedural success in experienced hands is high and complications are rare. Potential complications include device embolization, tamponade as a result of device erosion into the atrial or aortic wall, residual shunting, or atrial arrhythmias. ASD device mismatch is encountered in 2% to 5% of cases. Other rare complications include vascular access complications, sizing balloon rupture, and entrapment of right atrial structures. Chest discomfort or new onset of arrhythmia may be clues to device erosion or embolization and should prompt urgent echocardiographic evaluation.

D. Outcomes. Most patients demonstrate improved functional class and exercise capacity after a successful closure. Several observational studies have demonstrated an improvement in overall long-term survival. Timely ASD closure prevents the development of right heart failure and pulmonary hypertension. There has been evidence of reduction in the size of enlarged cardiac chambers with normalization of intracardiac pressures after successful ASD closure.

VII. VENTRICULAR SEPTAL DEFECT (VSD) CLOSURE

A. Background. Although isolated VSDs are a relatively common form of adult congenital heart disease, congenital VSDs of hemodynamic significance are rare, with a prevalence of 0.03% in the adult US population. More commonly, VSDs are acquired as a result of complication of MI, cardiovascular surgery, or chest trauma. Postinfarction ventricular septal rupture (VSR) is associated with > 90% mortality if left untreated. The postinfarction or traumatic VSRs may be located in the posterobasal (inferior infarct) or apical (anterior infarct) portions of the muscular ventricular septum and are typically irregular with multiple ruptures in necrotic myocardium that are prone to rupture or expansion. This presents significant challenges with respect to surgical as well as transcatheter repair.

Percutaneous VSD/VSR closure involves devices that are similar to those described for ASD closure. The device is positioned under fluoroscopy and echocardiographic guidance (TEE and/or ICE as needed) such that the two disks lie on either side of the ventricular septum and the waist lies in the septal defect. The width of the connecting waist determines device sizing.

B. Procedure. There are two devices that are approved for closure of congenital muscular VSDs: the CardioSEAL (NMT Medical, Boston, MA) and the Amplatzer muscular VSD occluder device (AGA Medical, Golden Valley, MN). There is a specially designed Amplatzer postinfarction muscular VSR occluder device, which is currently under investigation in the United States. It is similar to its congenital counterpart, except for a longer waist,

large disk diameter, and a larger waist diameter. In patients with postinfarct VSR, it may be necessary to use an atrial septal occluder, as the distance between the disks of the VSD occluder device may be too large. Again, this would be considered an "off-label" usage.

VSD closure can be achieved via the retrograde approach from the left ventricle or via the femoral or jugular vein. The VSD is crossed using a diagnostic catheter and wire, with the wire then externalized to the artery (if approached from the right ventricle) or vein (if approached from the left ventricle) to create a continuous arteriovenous (AV) loop. A delivery catheter containing the device is subsequently delivered over the loop. Under fluoroscopic and echocardiographic guidance, proper alignment and position are confirmed and the device is subsequently deployed.

C. Complications. The major complications of transcatheter VSD closure include device embolization, air embolism, residual shunting, defect enlargement, complete heart block requiring pacemaker implantation, arrhythmias, valvular regurgitation due to impingement, and intravascular hemolysis.

D. Outcomes. The results of transcatheter closure of congenital VSDs are encouraging; however, the closure of postinfarction VSR has yielded disappointing results in several studies. Although surgery has been recommended as the gold standard for the repair of postinfarction VSD, emergent surgical repair carries an operative mortality of about 50%. This often leads surgeons to recommend delaying the surgery for at least 2 weeks after the initial ischemic event, which may result in a lesser operative mortality and improve the chance of success. Due to this, several centers have attempted transcatheter VSR closure in patients who are either not surgical candidates or too unstable to survive the "waiting period." Data from observational studies have reported variable success, with mortality rates ranging from 20% to 100%.

VIII. LAA OCCLUSION

A. Background. AF is associated with 15% of all ischemic strokes. Autopsy studies have shown that up to 90% of the thrombi in nonvalvular originate in the LAA. Although warfarin has been demonstrated to reduce the rate of stroke in patients with AF, there are several limitations, including risk of bleeding, pharmacologic interactions, and need for prothrombin time (international normalized ratio [INR]) monitoring. In several patients, the use of warfarin may be contraindicated, necessitating another method of stroke prevention.

The LAA orifice is located between the left ventricle and the upper left pulmonary vein, extending over the atrioventricular groove toward the left circumflex coronary artery. Surgical amputation and exclusion of the LAA have been demonstrated to reduce the risk of stroke after MV surgery, without any significant impact on the rate of postoperative AF. In addition, LAA exclusion performed thoracoscopically by stapling the base of the LAA was found to be efficacious in small observational studies. Given the favorable location of the LAA for percutaneous closure, a number of methods have been developed.

B. Procedure. There are three devices with significant human experience available for LAA occlusion: the Percutaneous LAA Transcatheter Occlusion (PLAATO) device (ev3, Plymouth, MN), the Amplatzer Cardiac Plug (ACP) (AGA Medical, Golden Valley, MN), and the WATCHMAN device (Altritech Inc., Plymouth, MN). The WATCHMAN and ACP devices have CE Mark approval. The PLAATO device is available in several sizes ranging from 15 to 32 mm, the ACP device ranges from 16 to 20 mm, and the WATCHMAN device is available from 21 to 33 mm. The size and the shape of the LAA should be determined using TEE. Generally, the PLAATO device should be oversized by 20% to 40% and the WATCHMAN device by 10% to 20% for a good result.

The devices are generally implanted using 14F femoral venous access. A transseptal puncture is performed under fluoroscopic and TEE guidance. The device delivery system allows for collapse, repositioning, or removal of the device in case of unsatisfactory result. Adequacy of the LAA occlusion (defined as mild to absent leak) is confirmed using radiopaque contrast injection into the LA cavity.

C. Complications. The complications of the procedure include pericardial effusion, cardiac tamponade, residual leakage, or major vascular complications requiring transfusion.

D. Outcomes. In a large series of AF patients undergoing LAA occlusion with PLAATO, the observed annual stroke rate was 2.2%, which represented a 65% relative risk reduction with the PLAATO device. Similarly, the PROTECTion in patients with Atrial Fibrillation (PROTECT-AF) trial has demonstrated the non-inferiority of the WATCHMAN device compared with warfarin therapy for stroke prevention in patients with nonvalvular AF, despite a small increase in periprocedural complications in the device group. The WATCHMAN continued access registry demonstrated a substantial learning curve, with a reduction from 5.0% to 2.2% for pericardial effusion and 0.9% to 0.0% for stroke and increase from 89% to 95% for procedural success. By the same token, medical comparator groups are not ideal, with only half of patients in the PROTECT-AF trial demonstrating therapeutic INR. As with all other procedures, patient selection will be important to maximize benefits until we have a better sense of safety and outcomes.

IX. ALCOHOL SEPTAL ABLATION (ASA).

Septal myectomy is considered the gold standard for the treatment of HOCM. ASA has emerged as an attractive, less invasive alternative to myectomy for HOCM that is applicable to those patients who cannot or do not want surgery. Over the last 15 years, the number of ASA procedures done worldwide has surpassed the total number of myectomies performed in the last 50 years. ASA may be considered in patients who have clear evidence of septal hypertrophy (> 18 mm) projecting into the left ventricular outflow tract (LVOT), patients who have dynamic LVOT obstruction (gradient > 50 mm Hg at rest or upon provocation), and patients who have been refractory to medical therapy. Patients with coexistent abnormalities of mitral apparatus are best treated by surgery rather than ASA.

Selective coronary angiographic studies have demonstrated that the septum contributing to the LVOT obstruction is often supplied by the first septal perforator arising from the left anterior descending coronary artery. ASA entails creating a controlled myocardial necrosis by injecting alcohol into the first septal perforator. Postablation, the LVOT gradient demonstrates a triphasic response. There is an immediate reduction in the LVOT gradient after a successful procedure, attributable to the loss of septal contractility and myocardial stunning. Over the next few days, there is an increase in the LVOT gradient due to recovery of the stunned myocardium. The more permanent decrease in LVOT gradient happens over the course of the next few months secondary to myocardial thinning and septal remodeling.

A. Procedure. ASA is performed via femoral arterial access. A guiding catheter is introduced into the left main coronary artery and a guidewire advanced to the septal perforator of interest. Subsequently, a short "over the wire" (OTW) balloon is advanced to the septal perforator and inflated to obstruct backflow of alcohol from the septal to the left anterior descending artery. Angiographic contrast is injected through the balloon to ensure that there is absolutely no backflow into the LAD. Since transient heart block is common during the procedure, a temporary pacemaker is usually inserted.

Echocardiographic contrast is then injected through the OTW balloon in order to map the myocardium that would infarct as a result of ASA. This is an important step, as it helps determine the appropriateness of the procedure and helps in selecting the optimal branch for alcohol injection. Subsequently, 1 to 2 cc of alcohol is injected slowly through the balloon, with the balloon staying inflated for 5 minutes. Intravenous analgesia should be administered, as alcohol injection causes a short-lived but intense discomfort. The balloon is then deflated and removed. A final coronary angiogram is performed to verify lack of septal flow, and echocardiographic gradient is reassessed.

B. Complications. Besides the routine vascular complications that may arise in any interventional procedure, new-onset right bundle branch block is a significant complication of this procedure and is reported in up to 50% of patients in some

series. Complete heart block requiring a need for a permanent pacemaker may occur in about 10% of patients undergoing ASA. The other potential long-term complication includes ventricular arrhythmias, hypothesized to arise as a result of creation of arrhythmogenic myocardial scar. Recent meta-analyses have failed to demonstrate significant differences in ventricular arrhythmias between myectomy and ASA.

C. Outcome. Although there are no randomized comparisons between septal myectomy and ASA, large meta-analyses of observational data indicate no significant differences between the two modalities in terms of mortality and improvement in functional status postprocedure. The caveat of ASA is an increased incidence of conduction abnormalities and a small yet significantly higher LVOT gradient postprocedure.

X. PERCUTANEOUS PVL CLOSURE

A. Background. PVL is a rare but serious complication that may arise after surgical MVR or more rarely after SAVR. Although most PVLs are small and remain relatively asymptomatic, more than 10% of patients undergoing MVR or SAVR may develop large symptomatic PVLs with serious clinical consequences such as heart failure, endocarditis, or hemolytic anemia. Most PVLs become clinically apparent within 1 year after valve surgery, but a significant proportion may not require any definitive treatment till later. Several risk factors, including extensive annular calcification, evidence of endocarditis, large atria, renal failure, and older age, have been identified that may predispose a valve to develop PVL postsurgery.

Surgical intervention is typically the standard of care in management of patients with symptomatic PVL; however, reoperation is associated with a mortality rate of approximately 16%. Transcatheter closure of symptomatic PVL in a relatively small number of high-risk patients has been attempted in several centers over the last two decades. The devices approved for closure of other intracardiac defects like ASD, VSD, and PDA have been utilized in an off-label fashion for transcatheter PVL closure. We most commonly use an Amplatzer VSD occluder and/or Amplatzer vascular plug for these defects.

B. Procedure. In order to deploy an occlusion device across a PVL, it is first necessary to cross the defect with a delivery catheter. Aortic PVLs are generally crossed in a retrograde fashion from the femoral artery. The mitral PVL may be crossed in retrograde fashion from the femoral artery via the left ventricle, in the antegrade fashion by advancing a catheter from the right atrium into the left atrium via transseptal puncture, or via direct transapical access. Similar to percutaneous VSD/VSR closure, creation of an AV loop is usually mandatory to form a supportive rail for the passage of equipment. In addition to the use of fluoroscopy, TEE, and ICE during the procedure, three-dimensional echocardiography has recently gained popularity for optimal anatomical characterization and guiding device placement.

In the retrograde approach for mitral PVL closure, a diagnostic catheter (such as an internal mammary artery or JR4 catheter) is placed in the left ventricle. Subsequently, a 0.035" × 260 cm floppy glidewire is used to cross the defect, and the catheter is advanced over this wire into the left atrium. To provide adequate support for the device delivery catheter, an AV loop is typically established during this procedure; transseptal puncture and a GooseNeck snare are used to externalize the wire to form a continuous AV loop. Subsequently, the closure device is introduced through a delivery catheter from the venous side, while withdrawing the glidewire ("chasing the wire"). The device is subsequently deployed across the PVL in a standard fashion.

In the antegrade approach, transseptal puncture is carried out first. We typically use an Agilis steerable catheter (St. Jude Medical) to navigate the left atrium and direct the wire toward the defect. The location of the transseptal puncture is also highly variable and is directed by the location of the PVL. Through this catheter, a wire (preferably a 0.035″ glidewire) is advanced to cross the defect, and subsequently the catheter is advanced over this wire into the left ventricle. Subsequently, there is sequential delivery of increasingly supportive catheters (4F Bernstein, 6.5F JB1, Cook Medical) over more supportive wires (floppy glidewire, stiff glidewire, Amplatz

ES) to facilitate the placement of the device delivery sheath into the left ventricle via the PVL defect. Again, creation of an AV loop by externalizing the wire at the femoral artery or via the LV apex is usually necessary. The PVL occluder device is deployed in a standard fashion.

C. Complications. Transcatheter mitral PVL closure has had variable success. The initial technical success has ranged between 60% and 90%, with up to a 40% reintervention rate. Immediate and delayed device-related complications have been described as a result of technical failure. The early technical failure happens due to device impingement on nearby critical structures, and the delayed technical failure happens as a result of device embolization. Persistent PVL and/or its associated sequelae (i.e., CHF and hemolytic anemia) may be encountered after PVL closure. Although no procedure-related deaths have been described in any series, rare instances of strokes, dysrhythmias, and cardiac perforation have been described.

D. Outcomes. Transcatheter PVL closure is one of the most challenging structural heart disease interventions. The long-term outcomes after transcatheter PVL closure largely depend upon surmounting the limitations imposed by the current nonspecific devices for PVL closure, as well as challenges in imaging of the area of interest. Over the long-term follow-up described in a few relatively large case series, resolution of hemolysis was reported in 60% to 83% of patients, improvement in CHF symptoms was reported in 50% to 100% of the patients, and repeat surgery was required in only 4% to 18% of the individuals. The incidence of long-term mortality has ranged from 25% to 30% over 3 to 36 months of follow-up across various studies.

CHAPTER 67

Kia Afshar

Transthoracic Echocardiography

I. INTRODUCTION. Transthoracic echocardiography is a reliable and versatile tool for the assessment of cardiac structure, function, and hemodynamics. It has advantages over other cardiovascular imaging modalities in that it is relatively inexpensive, does not incur radiation exposure to the patient, is noninvasive, displays live real-time images, and is widely available. Common indications and corresponding aims of the echocardiographic evaluation are listed in Table 67.1.

II. BASIC PRINCIPLES OF ECHOCARDIOGRAPHY. Sound waves consist of mechanical vibrations that produce alternating compressions and rarefactions of the medium through which they travel. **Ultrasound** consists of sound waves in the frequency range that is higher than what is audible by humans (> 20,000 Hz). All waves can be described by their frequency (f), wavelength (λ), velocity of propagation (v), and amplitude. The velocity of ultrasound in soft tissue (e.g., myocardium and blood) is 1,540 m/s. Frequency is defined by the number of cycles occurring per second (cycles/second or Hz) and wavelength is measured in meters (m). Velocity, frequency, and wavelength are described by the following relationship:

$$\textbf{Velocity} = \textbf{frequency} \times \textbf{wavelength} \quad \textbf{or} \quad v = f \times \lambda$$

The typical adult echocardiographic examination uses a transducer with ultrasound frequency between 2.5 and 3.5 million Hertz (MHz). Based on the equation above, a 3-MHz transducer results in an ultrasound wavelength of approximately 0.50 mm. This has important implications since image resolution cannot be > 1 to 2 wavelengths (e.g., 1 mm with a 3-MHz transducer). In addition, the depth of penetration of the ultrasound wave is directly related to the wavelength, with shorter wavelengths penetrating a shorter distance. Therefore, higher frequency transducers result in the use of shorter wavelengths that improve image resolution but at the cost of reduced depth penetration.

Transducers use a piezoelectric crystal to generate and receive ultrasound waves. A piezoelectric substance has the property of changing its size and shape when an electric current is applied to it. An alternating electrical current will result in rapid expansions and compressions of the material and thus produce an ultrasound wave. The piezoelectric crystal also deforms in shape when an ultrasound wave strikes the material, resulting in the production of an electric current. The transducer, and the piezoelectric crystal, thus oscillates between a short burst of transmitting ultrasound waves, with a brief period of no ultrasound transmission when it awaits reception of the reflected signals.

Tissue harmonic imaging has become the standard imaging technique in many laboratories. It utilizes the principle that as ultrasound waves propagate through tissue, the waveform becomes altered by the tissue, with the generation of new waveforms of higher frequency but which are **multiples of the baseline fundamental frequency**. Setting the transducer to receive only harmonic sound waves that are multiples of the fundamental frequency improves image quality significantly. This image quality improvement is based

TABLE 67.1 Common Indications and Corresponding Aims of Echocardiographic Evaluation

Indications	Echocardiographic evaluation
Valvular heart disease	Valve morphology, regurgitation and/or stenosis severity and etiology, and ventricular size and function
Infective endocarditis	Vegetation, abscess, fistula, valvular function, and ventricular size and function
Coronary artery disease	Wall motion abnormalities, ventricular function, and mitral regurgitation/ventricular septal defect and other ischemic complications
Congestive heart failure	Systolic function, wall motion abnormalities, chamber size, valvular pathology, and diastolic function
Pericardial disease	Pericardial effusion, pericardial thickening ± calcification, and RV size and function
Cardiac tamponade	Pericardial effusion; RA diastolic collapse; RV early diastolic collapse; respiratory variations in mitral, tricuspid pulmonary venous, and hepatic venous flow; and IVC size and respiratory variation
Ascending aortic pathology	Aneurysm, atheroma, dissection or intramural hematoma, and aortic valve pathology
Pulmonary hypertension	RV systolic pressure, RV and LV function, and tricuspid, pulmonary, and mitral valve pathology
	Interatrial shunt and respiratory effects on IVC diameter
Systemic hypertension	LV function, LV wall thickness, and evidence of aortic coarctation
Embolic disease	LA and LV thrombus, mitral valve pathology, aortic atheroma, LV function, and interatrial shunt
Arrhythmias	LA and LV thrombus, ventricular size and function, atrial dimensions, and mitral valve pathology
Syncope	LV outflow tract obstruction, aortic and mitral valve pathology, LV function, and congenital abnormalities
Cardiac trauma	Ascending aortic dissection, ascending aortic aneurysm, and cardiac tamponade
Congenital heart disease	Congenital anomaly and shunt calculation
Critical illness	LV function, valvular pathology, pericardial effusion/tamponade, right-to-left shunt, and volume status

IVC, inferior vena cava; LA, left atrial; LV, left ventricular; RA, right atrial; RV, right ventricular.

on the fact that weak signals, which tend to be artifacts, create almost no harmonics. In addition, shallow structures, such as the chest wall, generate weak harmonic signals, whereas at depths of 4 to 8 cm, where the heart is located, maximal harmonic frequencies develop. These phenomena result in fewer near-field artifacts and better endocardial definition. One limitation of harmonic imaging is that valve leaflets appear thicker—an artifact generated during image processing that appears to be related to the rapid motion of the leaflets.

The steps involved in creating a final ultrasound image are transmission and reception of waves, conversion to electrical signals, filtering, and extensive computer processing. The details of image processing, formation of artifacts, advanced physics, and technical aspects of echocardiography are beyond the scope of this chapter, but these are briefly discussed in Section **VII**.

Patient and probe positioning, electrocardiographic lead placement, and transducer selection are the first steps to beginning the echocardiographic examination.

A. Patient and probe positioning. The probe can be held with the right or left hand depending on the patient side that one chooses to scan from. For the parasternal and apical positions, the patient should be in the left lateral decubitus position, with the left arm extended behind the head, as this brings the heart into contact with the chest wall. The subcostal and suprasternal views require the patient to be in the supine position.

B. Electrocardiographic lead placement. The ECG allows identification of arrhythmias and timing of cardiac events during the echocardiographic examination, and it is used as a timing marker for digital recording of images. Typically, digital "clips" are set to record a predefined number of cardiac cycles (usually one but sometimes two), with timing based on the ECG. It is important that irregular beats be identified and excluded from the analysis. For example, a postectopic beat will falsely increase the two-dimensional (2D) assessment of ejection fraction (EF) and the Doppler assessment of transaortic gradient. In general, any Doppler index requires the average of at least three measurements. For patients in atrial fibrillation, 7 to 10 beats should be averaged. For patients with very high heart rates, or with a noisy electrocardiographic signal, the digital clips can be set to record for a predefined period of time (usually 2 seconds).

C. Transducer selection. The adult echocardiographic examination typically begins with a 2.5- to 3.5-MHz phased array transducer. Transducer frequency is important, as at higher frequencies spatial resolution improves but at the expense of reduced depth penetration. Higher frequency (3.0 to 5.0 MHz) transducers may be used in thin or pediatric patients or intraoperatively for epiaortic scanning. Therefore, for optimal 2D resolution, select the highest frequency transducer that will provide adequate far-field penetration.

With regard to transducer frequency for the Doppler examination, lower frequency transducers can record higher velocities (see Doppler equation later in the chapter). The Pedoff probe is a continuous-wave (CW), nonimaging probe (typical frequency being 1.8 MHz) used mainly to detect higher velocity profiles and confirm velocities obtained by other imaging methods.

III. IMAGING MODALITES IN STANDARD ECHOCARDIOGRAMS

A. M-mode. Prior to 2D imaging, the echocardiogram was obtained when the transducer sent an ultrasound wave along a **single line** and then displayed the amplitude of reflected signal as well as the depth of that signal on an oscilloscope. This was called an A-mode echocardiography. When these line-of-sight ultrasound images were plotted with respect to time, "motion" mode, or M-mode, was produced. Despite the increasing emphasis on 2D imaging, the M-mode display remains a complementary element of the transthoracic examination. Its **high sampling rate** of approximately 1,800/s, compared with 30/s for 2D echocardiography, provides **excellent temporal resolution**, and thus it is very **useful in the timing of subtle cardiac events** that can be missed by the naked eye in 2D imaging. Rapidly moving structures such as the aortic valve, mitral valve, and endocardium have characteristic movements in M-mode. Deviations from these, such as diastolic fluttering of the mitral valve in aortic regurgitation (AR) and systolic aortic valve notching in dynamic left ventricular outflow tract (LVOT) obstruction, may be the only way to detect underlying dysfunction when they are not appreciated in other imaging modalities.

M-mode also has a great spatial resolution along the single line and can be used for precise size measurements such as ventricular dimensions in systole and diastole. The M-mode image is displayed like a graph, with **time on the *x*-axis and distance from the transducer on the *y*-axis**, with the structures closest to the transducer at the top of the image. In order to align the line of sight accurately, **2D imaging should be used to position the M-mode cursor** through the structures of interest.

B. Two-dimensional imaging. Two-dimensional imaging provides the **tomographic views** that are envisioned when one thinks of a transthoracic echocardiogram. It not only provides various 2D planes of cardiac structures but also acts as the platform that guides the M-mode and Doppler portions of the examination.

The 2D echocardiographic image is essentially the scan line from M-mode that, instead of having a fixed line of sight, is swept back and forth across an arc. After complex manipulation of the **data received by the transducer from the multiple scan lines**, a 2D tomographic image is generated for display.

Depending on the depth of the image, a finite amount of time is needed for each scan line to be sent and received by the transducer. As opposed to M-mode that has only one scan line and can provide over 2,000 frames/s, 2D echocardiographic imaging can utilize 128 scan lines but at the expense of a lower rate of 30 frames/s. Faster frame rates can be obtained by electronic manipulation using parallel processing on current ultrasound machines. Doppler overlay of the 2D image tends to slow down the frame rate. This **reduction in temporal resolution** reinforces the need for M-mode to complement 2D imaging in echocardiography, especially for rapidly moving structures and in precise timing of events.

C. Doppler echocardiography. The introduction of Doppler technique to echocardiography not only added new imaging capabilities but also transformed echocardiography into a modality that could provide **hemodynamic assessment** of the heart. Echocardiography has now become the preferred method, and in some cases the gold standard, over cardiac catheterization for certain hemodynamic assessments.

1. Doppler principles. The Doppler principle states that sound frequency increases as the sound source moves toward the observer and decreases as the source moves away. The change in frequency between the transmitted sound and the reflected sound is termed the **Doppler shift**. This phenomenon is appreciated daily when an ambulance's siren becomes higher pitched, due to the increase in wave frequency, as it approaches the observer and then lower pitched once it has passed. This Doppler frequency shift directly relates to the velocity of the red blood cell by the following **Doppler equation**:

$$v = \frac{c\,(f_R - f_T)}{2f_T\,(\cos\,\theta)}$$

where v = velocity, f_R = frequency received, f_T = frequency transmitted, c = speed of sound in blood (1,540 m/s), and θ = angle between moving object and ultrasound beam.

The cos θ in the Doppler equation makes the calculation of velocity depending on the angle between the beam and the moving structure (red blood cell). Echocardiography machines do not typically incorporate the angle for calculating the resultant velocity, and thus the goal is to have the angle between the ultrasound beam and the blood flow jet of interest to be as close to zero as possible (cos 0 = 1). When this is not possible, the angle should be < 20°, so that the true flow velocity is underestimated by < 6% (cos 20 = 0.94). Adhering to this requirement sometimes mandates off-axis or unusual 2D images to align the Doppler ultrasound signal with desired target. Reference Doppler velocities in the adult examination are given in Table 67.2.

TABLE 67.2 Normal Echo Dimensions in Adults

Factor	Ref. range (cm)	Factor	Ref. range (cm)
(i) Parasternal long axis (M-mode or 2D)			
LV end-diastolic diameter	3.5–5.7	LV end-systolic diameter	2.3–4.0
Septal thickness (ED)	0.6–1.1	Posterior wall thickness (ED)	0.6–1.1
Aortic root (ED—M-mode)	2.0–3.7	Left atrium (ES)	1.9–4.0
RV end-diastolic diameter	1.9–3.8		
Aortic annulus (systole—2D)	1.4–2.6	Midascending (2D)	2.1–3.4
(ii) Four-chamber view			
LV volume (ED) (cm^3)	96–157	LV volume (ES) (cm^3)	33–68
Ejection fraction (%)	59 ± 6		
Left atrial area (cm^2)	< 20		
(iii) Doppler velocities			
Mitral E wave (< 50 y) (cm/s)	72 ± 14	Mitral E wave (> 50 y) (cm/s)	62 ± 14
Mitral A wave (< 50 y) (cm/s)	40 ± 10	Mitral A wave (> 50 y) (cm/s)	59 ± 14
Deceleration time (ms)	140–210		
Ascending aorta (m/s)	1.0–1.7	LV outflow tract (m/s)	0.7–1.1
Pulmonary artery (m/s)	0.5–1.3		
Pulmonary vein S wave (cm/s)	56 ± 13	Pulmonary vein D wave (cm/s)	44 ± 16
Pulmonary vein A reversal (cm/s)	32 ± 7		

ED, end-diastole; ES, end-systole; LV, left ventricular; RV, right ventricular.

2. **Spectral analysis** is the term used to describe the way in which pulsed-wave (PW) Doppler and CW Doppler are displayed. By convention, the horizontal axis reflects time and is placed in the middle of the screen with upward deflections representing frequency shifts toward the transducer and downward deflections for frequency shifts away from the transducer. The vertical axis represents the blood flow velocity (or frequency shifts), with the density of pixels on a gray scale reflecting the amplitude of the signal. The final result is that at each time-point the spectral analysis shows blood flow direction, velocity/frequency shift, and signal amplitude.
   a. **PW Doppler.** The purpose of PW Doppler mode is to measure the Doppler shift, and thus velocity, at a **specific location of interest within a small sample volume** (e.g., mitral inflow velocity at the mitral valve leaflet tips, systolic velocity at the LVOT, and blood flow within the pulmonary veins). In this mode, a **single crystal** sends short bursts of ultrasound waves at a

specific pulse repetition frequency (PRF) to a specific location, which are reflected from moving blood cells at this location and received by the same crystal. The maximal velocity that can be measured is limited by the time required to transmit and receive the ultrasound wave. This is called the **Nyquist limit** (one-half of the PRF). If a velocity greater than the Nyquist limit is measured, the signal appears as a wrap around the baseline, known as **signal aliasing**. Hence, the peak velocity is limited by the depth of the area of interest and also by the transducer frequency (inverse relationship according to the Doppler equation; see previous text). **PW Doppler has excellent spatial/depth resolution, but it has limited capacity to measure high velocities due to the Nyquist limit**. It is, therefore, used primarily to measure low-velocity flow (< 2 m/s) at specific sites in the heart.

b. **CW Doppler.** CW Doppler employs **two crystals, one continuously sending ultrasound waves and the other continuously receiving the waves**. It measures Doppler shift **along the entire beam**, rather than at a specific location. Unlike PW Doppler, CW Doppler measures the **maximal velocity along the entire ultrasound beam** but it does not localize the precise position of that peak velocity. However, this is often apparent anatomically or can be deduced using PW Doppler or color flow Doppler. **In general, CW Doppler is used to assess high-velocity flow and PW Doppler is used to measure low-velocity flow in specific areas**. Clinical applications of PW versus CW Doppler are listed in Table 67.3.

c. **Color flow imaging.** Although spectral (pulsed-wave and continuous-wave) Doppler imaging is superior for accurate measurement of specific intracardiac blood flow velocities, the best way to visualize the overall pattern of intracardiac blood flow is with color flow imaging. Color flow Doppler is based on the principle of PW Doppler, with multiple sampling volumes at

TABLE 67.3 Differences and Uses of Pulsed-Wave Doppler and Continuous-Wave Doppler

Factor	Pulsed wave	Continuous wave
Transducer crystal	Same transmitting and receiving	Different transmitting and receiving
Spatial resolution	Excellent—localizes to precise point	Poor—may be anywhere along the entire beam
Ability to measure high velocity (> 2 m/s)	No (limited by Nyquist)	Excellent
Uses	Mitral inflow	Gradients in aortic stenosis
	Pulmonary venous flow and LVOT flow	Gradient and pressure halftime in mitral stenosis
	Hepatic vein flow	Peak velocity in mitral regurgitation and measurement of dp/dt
	Tricuspid inflow	
		TR velocity—estimate RV systolic pressure

LVOT, left ventricular outflow tract; RV, right ventricular; TR, tricuspid regurgitation.

varying depths along a single scan line. A full-color flow map is generated by combining multiple scan lines along the areas of interest. To accurately estimate the velocity along a given scan line, the instrument compares the Doppler shift changes from several successive pulses (typically eight), and this is known as the **burst length**. Where Doppler shifts are detected, color pixels are displayed at that location with the different colors representing the different degrees of Doppler shift based on a predetermined color spectrum. Tradition has set **blood velocity toward the transducer as shades of red and blood flow away as shades of blue (Blue Away)**.

Since this modality uses properties based on PW Doppler technology, color flow Doppler has limitations similar to those of PW Doppler for velocity determination. When the flow velocity is higher than the Nyquist limit (indicated on the color map), color aliasing occurs (depicted as color reversal, red to blue or blue to red transition). The fact that color aliasing occurs can actually provide important hemodynamic information, such as identification of flow acceleration or calculation of the proximal isovelocity surface area (PISA), which is discussed in Section **VI.C.6**.

d. Tissue Doppler imaging (TDI). TDI is based on adjusting standard Doppler to focus primarily on the low-velocity, high-amplitude **motion of the myocardium** (usually < 20 cm/s) instead of the high-velocity, low-amplitude motion of red blood cells. Decreasing the filters (which normally eliminates low-velocity signals) and the Doppler transmit gain (which excludes the low-amplitude blood signals) results in the Doppler focusing primarily on myocardial motion. TDI can be displayed as either PW Doppler, typically at one aspect of the mitral annulus (usually septal or lateral) or by color flow TDI mapping of the entire myocardial area of interest (Fig. 67.1). TDI has primarily been used as an adjunct for the evaluation of left ventricular (LV) diastolic function, where the mitral annular TDI pattern shows a systolic (S) wave toward the transducer and two diastolic waves away from the transducer (corresponding to early relaxation and late atrial diastolic myocardial motion, labeled as E′ and A′) (Fig. 67.2 and Table 67.4). With worsening diastolic function, E′ velocity decreases and is directly proportional to the rate of relaxation. TDI annular velocities decrease with age and may be affected by a myocardial infarction in the region adjacent to the annulus or surgery of the mitral valve. Therefore, TDI can be used to help differentiate

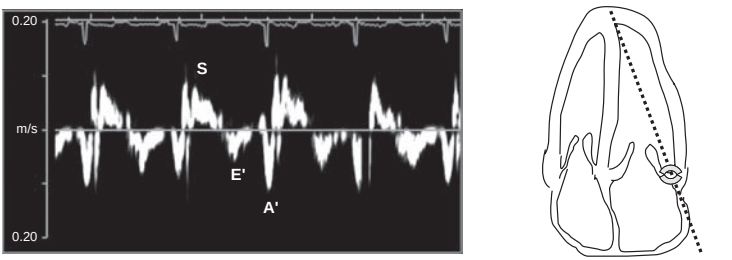

FIGURE 67.1 Tissue Doppler imaging (TDI) for diastolic function recorded from the apical four-chamber window using a 2-mm sample volume positioned in the lateral wall 1 cm from the mitral annulus. The TDI signal is toward the transducer in systole (S) as the myocardium moves toward the apex. In diastole, the myocardial velocity is directed away from the transducer first with early diastolic filling (E′) and then with atrial contraction (A′).

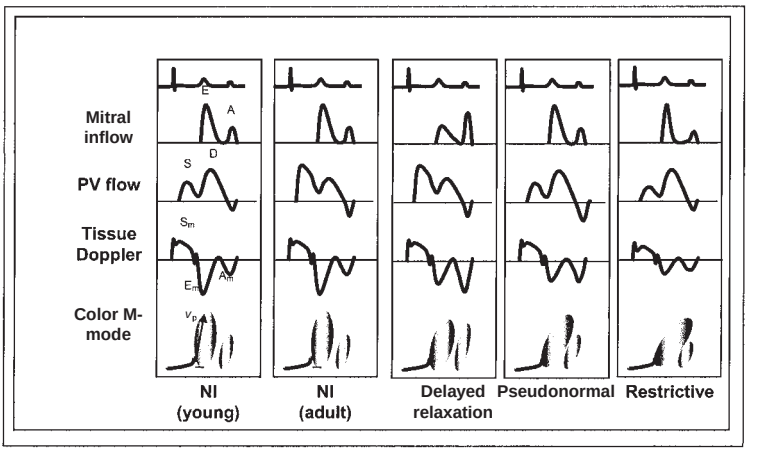

FIGURE 67.2 Diastolic function/dysfunction staging. PV, pulmonary vein; Tissue Doppler: mitral annular velocity by Tissue Doppler; NI, normal; S, systolic; D, diastolic; S_m, systolic annular velocity; E_m, early diastolic annular velocity (E′); A_m, atrial annular velocity (A′); V_p, velocity of propagation; E, early mitral inflow velocity; A, atrial kick mitral inflow velocity.

a normal mitral inflow pattern (normal E′) from a pseudonormal filling pattern (reduced E′) (Fig. 67.2 and Table 67.4). TDI can also be used to assess LV filling pressures, myocardial deformation, and ventricular dyssynchrony.

D. Color M-mode (CMM). This technique, whereby color flow Doppler is imposed on an M-mode image, permits excellent spatiotemporal distribution of velocity (color) data, although it is limited to the defined scan line. It is a valuable adjunct in the timing of cardiac events, which may not be readily appreciated by 2D and color flow imaging alone. Its primary use has been in evaluating diastolic filling pattern where the LV inflow CMM pattern typically has two appreciable waves, the first demonstrating the early passive filling wave and the second later wave resulting from atrial contraction (Fig. 67.2). The slope of the early filling wave (velocity of propagation, V_p) is primarily

TABLE 67.4 Diastolic Function/Dysfunction Staging

	Normal young	Normal adult	Normal elderly	Delayed relaxation	Pseudonormal filling	Restrictive filling
Stage	Normal	Normal	Normal	I	II	III
E/A ratio	> 1 (often > 2)	> 1	< 1	< 1	1–2	> 2
DT (ms)	< 220	< 220	> 220	> 220	150–200	< 150
S/D ratio	< 1	≥ 1	> 1	> 1	< 1	< 1
Ar (cm/s)	< 35	< 35	< 35	< 35	> 35	> 25
V_p (cm/s)	> 55	> 55	< 55	< 55	< 45	< 45
E′ (cm/s) (E annulus)	> 10	> 8	< 8	< 8	< 8	< 8

dependent on the rate of relaxation and is reduced with delayed relaxation. It is useful for differentiating a normal mitral inflow pattern (normal V_p) from a pseudonormal filling pattern (where impaired relaxation results in delayed flow propagation into the left ventricle, slower V_p) (Fig. 67.2 and Table 67.4).

Other uses of CMM are the accurate measurement of AR jet diameter in the LVOT in the parasternal views and, with its superior temporal resolution, detection of diastolic mitral regurgitation (MR), which may be seen in certain conditions (severe acute AR, advanced diastolic dysfunction, and complete heart block).

IV. TOMOGRAPHIC VIEWS AND CARDIAC ANATOMY. Most echocardiography laboratories have similar protocols for acquisition of a complete echocardiogram with only slight differences. Each echocardiographic view is labeled first by the transducer position (parasternal, apical, subcostal, and suprasternal) followed by the tomographic view of the heart (long axis, short axis, four chamber, and two chamber). To acquire these different views, the transducer is placed on different parts of the body and adjusted with rotation and angulation to optimize the final image. Standard imaging planes are illustrated in Figures 67.3 to 67.8; see Table 67.5 for standard examination protocol and Table 67.6 for useful examination tips.

A. Parasternal. The parasternal position is typically obtained by placing the transducer at the left of the sternal border in the third or fourth intercostal space. The optimal position for the patient is usually the left lateral decubitus position, but sometimes some hybrid between the steep left lateral and supine position is required to optimize the view. This position allows imaging of the long axis as well as the short axis of the heart.

TABLE 67.5 Standard Transthoracic Examination

1. **PLAX**
   - Position transducer in third or fourth intercostal space parasternally (ridge toward right shoulder)
   - Color Doppler—mitral and aortic valve flow and interventricular septum (in cases of ventricular septal defect)
   - M-mode—three levels (below mitral leaflets, midmitral leaflets, and aortic valve)
   - Move up an intercostal space to get better view of ascending aorta
   - Tilt transducer inferomedially to assess RV inflow. Color Doppler to assess tricuspid regurgitation and CW Doppler to estimate RVSP
2. **PSAX**
   - Rotate transducer 90° clockwise from PLAX and tilt transducer from superior to inferior (LV apex view, mid-LV view, mitral valve view, and aortic valve level)
   - Color Doppler at mitral valve level (localize mitral regurgitation if present)
   - Color Doppler at aortic valve level (localize aortic regurgitation and assess flow in RVOT/pulmonic valve and tricuspid valve)
   - PW Doppler—RVOT (level of pulmonic valve annulus)
   - CW Doppler—RVOT/pulmonic valve and tricuspid valve (estimate RVSP)
3. **A4C**
   - Transducer at apex—ridge toward left (move laterally and inferiorly if necessary to get true apex)
   - Color Doppler—mitral flow and tricuspid flow
   - Measure PISA if mitral regurgitation (zoom, decrease Nyquist, and measure radius)
   - PW Doppler—mitral inflow—position at level of mitral leaflet tips (gate 1–2 mm)

TABLE 67.5 Standard Transthoracic Examination (*Continued*)

- PW Doppler—PV (usually right upper PV)—1–2 cm into vein (gate 3–4 mm)
- CW Doppler—across mitral valve (stenosis and/or regurgitation and to calculate PISA)
- CW Doppler—tricuspid flow (estimate RV systolic pressure)
- Tilt transducer anteriorly to obtain "five-chamber view," i.e., open up aortic valve/LVOT
- Color Doppler—LVOT/aortic valve
- PW Doppler—LVOT—at the level of the aortic annulus
- CW Doppler—LVOT/aortic valve
- Tilting transducer posteriorly will bring the coronary sinus in view (along AV junction, emptying into right atrium)

4. **A2C**
   - Rotate transducer ~60–90° anticlockwise
   - Tilt posteriorly and rotate clockwise to open out descending aorta
5. **Apical long axis (apical three chamber)**
   - Rotate transducer further 30–45° anticlockwise
   - Color Doppler—LVOT/aortic valve
   - Recheck CW Doppler across aortic valve if evaluating for aortic stenosis
6. **Subcostal view—patient supine and legs bent at knees**
   - Subxiphoid, midline, tilt anteriorly under sternum with groove toward patients left for four-chamber view
   - Color Doppler across interatrial septum to check for a PFO or ASD
   - Rotate transducer 90° from four-chamber view until groove is pointing anterosuperiorly
   - Same views as PSAX except rotated 90° clockwise
   - Sweep from left to right to get apical, midventricular, and aortic valve levels
   - IVC should be visualized when scan plane is directed toward the right midclavicular region with some counterclockwise rotation to open out long axis of IVC
   - Color Doppler—IVC flow
   - PW of hepatic veins (may need to angle posteriorly)
7. **Suprasternal view—patient supine and head tilted backward**
   - Transducer in suprasternal notch, with groove toward left (rotate to about 1 o'clock), parallel to trachea
   - Color Doppler in arch and upper descending aortas (especially if suspected coarctation)
   - PW Doppler in upper descending aorta (if assessing aortic regurgitation severity)
8. **Pedoff probe**
   - Especially for checking maximal aortic valve gradient in aortic stenosis
   - Apical position
   - Right upper sternal border (aortic stenosis)

A4C, apical four chamber; A2C, apical two chamber; AV, atrioventricular; ASD, atrial septal defect; CW, continuous wave; IVC, inferior vena cava; LV, left ventricular; LVOT, left ventricular outflow tract; PLAX, parasternal long axis; PSAX, parasternal short axis; PFO, patent foramen ovale; PW, pulsed wave; PV, pulmonary vein; RV, right ventricular; RVOT, right ventricular outflow tract, RVSP, right ventricular systolic pressure.

TABLE 67.6 Tips for Transthoracic Two-Dimensional Examination

1. **Optimize patient position** (left lateral with left hand above head) and **environment** (darkened room).
2. Ensure imaging in **harmonics** mode.
3. Consider **contrast** to improve endocardial delineation for technically difficult studies.
4. When parasternal and apical images are limited (body habitus, surgical drains, dressings, etc.), the **subcostal window** may be the only accessible window.
5. Consider **off-axis views** to enhance visualization of specific structures.
6. Obtain images at **end of expiration,** as the heart is closer to the transducer.
7. **Avoid foreshortening LV apex** (especially in A2C)—true apex may be more inferior and lateral than expected.
8. If there is a **concern of LV thrombus,** zoom and check with low-velocity color Doppler to ensure flow throughout. Consider contrast if unclear.
9. If an object is suspicious for an artifact, reassess in other imaging planes.
10. **M-mode** can be useful especially for the accurate timing of cardiac events (especially RV or RA collapse in the setting of possible tamponade or assessment of possible systolic anterior motion of the mitral valve).
11. Adjust transducer **frequency** to maximum that permits adequate far-field penetration/depth.
12. Set **time gain compensation** in the midrange with lower gain in the near field and higher settings in the far field to compensate for attenuation of the beam with increasing distance from transducer.
13. Use the least amount of **depth** that adequately shows the entire area of interest.
14. Adjust the **transmit gain/output** to optimize image brightness/quality—too low, everything appears black, too high results in a "white-out." Initially set it to high and then adjust downward.
15. Adjust the **"compress"/dynamic range**. Decrease if image quality is poor to produce high-quality contrast images. Increasing it will "soften" images. Typically as compress is increased, the transmit gain should be decreased to maximize the spectrum of the gray scale.
16. Adjust the **focus** (focal zone) to include the area of interest, as the beam is narrowest (improves image resolution) within this area, especially when imaging near-field structures (e.g., looking for an apical LV thrombus from the apical windows).
17. Set the **persistence** to low.

LV, left ventricular; A2C, apical two chamber; RA, right atrial; RV, right ventricular.

1. **Parasternal long axis (PLAX).** The PLAX tomographic view is traditionally the first view of a standard transthoracic echocardiogram. The ultrasound beam is lined up between the patient's right shoulder and the left flank. The right ventricular outflow tract (RVOT) is located at the top of the image, the aorta to the right, the inferolateral (or posterior) wall on the bottom, and the cardiac apex on the left. The anteroseptum is visualized between the RVOT and the LV cavity. Therefore, the PLAX view of the heart is similar to the sagittal view of the left ventricle if viewed from the patient's left side in the supine position. Tilting

the transducer's tail toward the left shoulder with slight clockwise rotation aims the ultrasound beam inferomedially and brings the right ventricular inflow into view. This is good for obtaining the tricuspid regurgitation (TR) velocity as well as viewing the tricuspid valve, RV apex, and the right atrium.

2. **Parasternal short axis (PSAX).** While the transducer is still in the parasternal position, rotating the transducer clockwise to approximately 90° displays the heart in the short axis. The ultrasound beam in this case is roughly from the left shoulder to the right flank. Using different degrees of transducer tilting, and occasionally moving up or down an intercostal space, results in four traditional views of the heart. On tilting from superior to inferior, the views obtained are aortic valve–RV outflow, mitral valve level, midventricle at the papillary muscles, and the LV apex. The images appear as if viewing the heart from the apex and looking through to the base; therefore, the septum is on the left, lateral wall on the right, the anterior and anteroseptal walls at the top, and the posterior–inferior walls on the bottom of the screen.

B. Apical. The apical position is obtained with the patient still in the left lateral position and the probe placed at the apical impulse. This position obtains images in the long axis of the heart.

1. **Apical four chamber (A4C).** The A4C view is obtained with the ultrasound beam transecting the thorax in a superior–inferior fashion. Most institutions orient the transducer to place the left ventricle on the right side of the screen and the right ventricle on the left side. The apex is at the top of the image and the atria at the bottom regardless of the orientation. The inferoseptal and anterolateral walls as well as apex of the left ventricle can be assessed in this view.
2. **Apical five chamber (A5C).** A slight rotation of the transducer introduces a fifth "chamber" in view, the proximal aorta. The aortic valve and LVOT also appear. This view allows for hemodynamic assessment of the LVOT and aortic valve as well as an additional view for aortic valve pathology.
3. **Apical two chamber (A2C).** Further rotation, 90° counterclockwise from the A4C view, obtains the A2C view. In addition to the left atrium, the LV anterior wall, inferior wall, apex, and mitral valve are also well visualized.
4. **Apical three chamber (A3C).** A slightly more counterclockwise rotation (approximately 30°) brings the aorta back into view, resulting in the A3C, or apical long-axis, view. This essentially has the same anatomical structures as those in the PLAX view with a different orientation. The apex is better visualized and the RVOT usually drops out of the image. Additional information on mitral and aortic valve hemodynamics can be obtained in this view, which is not ideally obtained in the PLAX view.

C. Subcostal. In a standard transthoracic examination, the subcostal view provides additional views of the ventricles, atria, and atrial septum that had been acquired in earlier portions of the examination (but now with a different orientation). However, in some patients with poor parasternal and apical views (e.g., hyperinflated lungs), the subcostal view may be the only way to obtain images of the heart since the parasternal and apical locations may have poor windows.

The subcostal position is located caudal to the xiphoid process, with the patient in the supine position. The transducer is placed in the midline nearly parallel to the long axis of the patient's body so that the ultrasound beam slices toward the spine. This shows the right ventricle at the top right, the left ventricle at the bottom right, and their respective atria on the left. Clockwise rotation along with inferior tilting brings the inferior vena cava (IVC) and hepatic veins into view, which are used for right-sided hemodynamic assessments.

In patients with very poor parasternal and apical windows, modified views from the subcostal position can be incorporated in the examination to gather the images from a different perspective.

D. Suprasternal. Placing the transducer in the suprasternal notch and pointing inferiorly can assess the ascending aorta, aortic arch, and descending aorta. Hemodynamics from this position can better characterize AR as well as the presence of coarctation.

V. ADVANCED ECHOCARDIOGRAPHIC TECHNIQUES

A. Contrast echocardiography. Contrast echocardiography is performed by injecting either **agitated saline** or one of the **commercially available contrast agents** into an arm vein. The choice of agitated saline versus commercial contrast agents depends on whether the goal is to visualize the right atrium and ventricle versus the left ventricle and myocardium. Both are microbubbles that reflect ultrasound waves and opacify intracardiac chambers. The size of the microbubbles relative to the pulmonary capillary diameter determines whether they cross to the left side of the heart or get trapped in the pulmonary circulation.

Agitated saline is sterile saline (preferably mixed with some blood), combined with a small quantity of air, which has been exchanged rapidly using a three-way stopcock between two syringes to create small bubbles. These relatively large (and unstable) bubbles are caught in the lung and do not routinely appear in the left side of the heart. However, after the bubbles are seen within the right atrium, their appearance in the **left atrium within three beats** of the cardiac cycle suggests a right-to-left **intracardiac shunt**—typically from a small patent foramen ovale. Contrast may appear in the **left atrium more than four beats** after it is seen in the right atrium, and this more likely signifies an **intrapulmonary shunt** rather than an intracardiac shunt. There is a small risk of embolic complications in the use of agitated saline. Care should be taken to avoid injecting larger air bubbles by inspecting the syringe closely prior to injection and ensuring that the bubbles are very small. Additionally, injecting contrast in a known large shunt should be avoided.

Modern commercial contrast agents consist of either an albumin-based shell containing perfluorocarbon gas (Optison) or a synthetic phospholipid shell containing perfluoropropane gas (Definity). These **microbubbles are much smaller** (the size of a red blood cell) and more stable; therefore, they can **cross the pulmonary capillaries and appear on the left side of the heart, where they opacify the LV cavity. Their primary uses are to improve endocardial definition** and to clarify the presence/absence of a suspected LV thrombus/mass. Ultrasound waves, especially those of higher power, destroy microbubbles; therefore, for optimal contrast imaging, it is important to reduce the mechanical index (the output of the machine), typically to 0.4 to 0.6.

Contrast also enhances Doppler signals, and agitated saline can be useful to augment the signal from TR to better estimate peak right ventricular systolic function (RVSP), whereas commercial microbubble products (Optison and Definity) can be used to enhance the Doppler envelope in patients with aortic stenosis when the image quality is suboptimal.

Contrast echocardiography was the subject of a black box warning from the FDA because of concerns of significant adverse vents in patients who received it. More recent data suggest that adverse events following contrast injection are no more common than in those in whom it is not used when appropriate adjustment for severity of illness is made. Nevertheless, the FDA has recommended that patients with pulmonary hypertension or unstable cardiac conditions such as recent myocardial infarction, unstable angina, decompensated heart failure, ventricular arrhythmia, or respiratory failure should be monitored closely for at least 30 minutes after its use. It is contraindicated when a fixed or even transient right-to-left shunt is present or with documented allergy to its components such as blood products or albumin in the case of Optison.

B. Three-dimensional (3D) echocardiography is now emerging as a realistic imaging modality with improving image quality on newer generation 3D machines. Images are obtained using a transducer that transmits and receives data simultaneously in a 3D volume. Either real-time 3D images or biplane (orthogonal) simultaneous 2D images can be obtained. The 3D data set can then be manipulated using different software packages to assess function and anatomy. It is of particular benefit for the localization of valvular abnormalities (especially for the complex 3D mitral valve structure), accurate LV volume calculation, guiding surgical interventions (e.g., mitral valve repair), and complex congenital heart disease. Three-dimensional echocardiography allows for a better assessment of the right ventricle, which has a complicated geometry that is sometimes difficult to assess using 2D echocardiography. Three-dimensional color flow imaging allows for a comprehensive assessment of vena contracta and areas of flow convergence (PISA), which can improve the quantification of valvular regurgitation. It has been documented to allow for a more rapid evaluation of mitral valve area (MVA) in mitral stenosis as compared with conventional 2D planimetry. With the present technology, image resolution remains inferior to 2D imaging.

C. Myocardial mechanics—tissue strain, strain rate imaging, and speckle tracking. Strain rate imaging allows for the estimation of regional myocardial deformation and, therefore, function. **Tissue strain, a dimensionless entity, is a measure of the relative deformation of tissue**. Myocardial deformation in a segment of interest is assessed with reference to the adjacent segment, avoiding errors introduced by translational motion and tethering. **Strain rate is the rate of the deformation between two adjacent points of interest along a scan line and is expressed in seconds**. A strain rate curve can be derived by analyzing many adjacent segments along a scan line. Doppler techniques for assessing strain are not always ideal due to angle dependence, signal noise, and the need for a high frame rate. Doppler-independent techniques such as **speckle tracking** use ultrasonic reflectors (speckles) within tissues that can be followed from frame to frame through the cardiac cycle. This method can be used to assess the radial deformation and torsion of the ventricle. Strain rate is a relatively preload-independent measure of regional myocardial function. Clinical applications include assessment of myocardial ischemia, viability, diastolic function, subclinical LV dysfunction in valve disease, and cardiac involvement in systemic diseases such as diabetes or amyloidosis.

D. Dyssynchrony. Dyssynchrony occurs when different areas of the ventricles contract in an irregular pattern spatially and temporally. It is primarily seen in patients with impaired systolic function and electrophysiologic conduction delays. M-mode, 2D imaging, color Doppler, and tissue Doppler have all been employed to assess the amount of dyssynchrony but no consensus exists on the optimal approach to evaluate ventricular dyssynchrony (see Chapter 56). Some useful measures include the following:

1. A difference in the time to peak velocity of > 65 milliseconds between opposing walls (basal segments in four-chamber, two-chamber, and three-chamber views yielding a total of six segments) using pulsed tissue Doppler.
2. A difference of 40 milliseconds in the interval from the QRS complex to the onset of flow in the RVOT versus the LVOT using pulsed tissue Doppler.
3. Using M-mode or speckle tracking, a difference of 130 milliseconds in the septal to posterior wall delay.

After the implantation of a resynchronization device, Doppler echocardiography is used for the optimization of programmed timing.

VI. SPECIAL TOPICS

A. Systolic function. Two-dimensional imaging is currently the primary echocardiographic means of determining systolic function of the heart. The most utilized

measurement is the EF. In the past, a common way of determining the EF was based on estimation by visual inspection. Recently, echocardiographic societies have recommended using standardized objective methods to minimize interobserver differences. LV volume is best measured using the modified Simpson's method (disk summation method). This involves tracing the LV area from two orthogonal views (typically A4C and A2C) and dividing the left ventricle into a number of cylinders of equal height. Total ventricular volume is calculated by adding up all the volumetric cylinders. All modern machines and digital echo reading systems have integrated software to create and combine the volume data after simply tracing the LV areas in both apical views. Based on the volumes measured in diastole and systole using this method, stroke volume (SV) and EF can be estimated from volume data obtained by **Simpson's method:**

Stroke volume (SV) = end-diastolic volume (EDV) – end-systolic volume (ESV)

$$EF = SV/EDV \times 100\%$$

$$\mathbf{EF = EDV - ESV/EDV \times 100\%}$$

Newer semiautomated methods in 3D echocardiography using full matrix-array transducers give accurate, reproducible assessments of LV volume and EF that are superior to 2D methods when magnetic resonance imaging is used as the gold standard.

Finally, newer methods of assessing systolic function are becoming important. For example, LV torsion is a newer index for assessing LV systolic function that uses speckle tracking. The difference between the clockwise rotation of the base of the heart and the counterclockwise rotation of the apex of the heart (approximately 12°) can be evaluated using speckle tracking. Global strain also appears to be a robust parameter for assessment of LV function. Normally, LV peak systolic strain is negative and averages to $-18.6 \pm 0.1\%$.

In addition to the assessment of EF for the evaluation of systolic function, an assessment of regional wall motion and thickness is crucial in understanding the mechanism of disease. This is based on the fact that certain cardiac disease processes cause nonuniform abnormalities (coronary artery disease and sarcoidosis) and others cause global insults (hypertension and familial cardiomyopathy). For example, an EF of 35% that has a thin and akinetic anterior and anteroseptal wall would suggest an old transmural myocardial infarction due to occlusion of the left anterior descending artery. However, an EF of 35% with no regional wall abnormalities and thick myocardial walls could suggest amyloidosis or hypertension as the cause of the systolic dysfunction. Strain technology allows the display of regional variation in this modality that may be useful in understanding the regional manifestations of systolic dysfunction. For instance, in amyloidosis, strain is often preserved at the apex, but it is diminished in other areas of the heart.

B. Diastolic function. Doppler echocardiography remains the primary modality for assessing LV diastolic function, primarily by integrating information obtained from PW Doppler of mitral inflow and pulmonary venous flow combined with 2D assessment of left atrial size. Addition of CMM and TDI modalities can help optimize the assessment of degree of diastolic dysfunction, and combined mitral inflow/CMM (E/V_p) and mitral inflow/TDI (E/E′) indices can be used to estimate LV filling pressures.

Traditionally, diastolic function was determined solely based on the assessment of mitral inflow pattern; however, with worsening diastolic function, a "pseudonormal" pattern appears (due to the opposing effects of delayed LV relaxation and elevated LV filling pressures), and this is indistinguishable from a normal diastolic filling pattern. Pulmonary venous flow can help differentiate these. Conventionally, the normal anterograde S/D pattern (S > D) should be reversed (S < D) in patients with pseudonormal LV diastolic filling, with an

increased retrograde atrial reversal velocity. However, optimal pulmonary venous flow images can be difficult to obtain, and flow patterns can be affected by other factors, including rhythm (atrial fibrillation) and valvular dysfunction (MR). Both CMM (delayed V_p) and TDI (reduced E′) are useful to help confirm a pseudonormal filling pattern. An additional important key factor in assessing LV diastolic function is left atrial volume indexed to body surface area, which is invariably increased with worsening diastolic function. Significant diastolic dysfunction is unlikely to exist with a normal left atrial volume index. Accurate assessment of diastolic function not only is important for diagnosis of patients with primarily LV diastolic heart failure but is also of major prognostic importance for patients with systolic heart failure.

C. Hemodynamics

1. Transvalvular pressure gradient. The **Bernoulli equation** allows measurement of relative pressure differences across valves, shunts, or the LVOT. In its complete form, the Bernoulli equation is too complex for routine clinical use, as it incorporates three main components, namely, convective acceleration, inertial term (flow acceleration), and viscous friction. In many clinical situations, the latter two components can be ignored, leaving the flow gradient across an orifice to be derived from the convective acceleration term alone:

$$\Delta P = 4 \times (V_2^2 - V_1^2)$$

where V_2 is the velocity distal to an obstruction and V_1 is the velocity proximal to an obstruction.

The flow proximal to a narrowed orifice (V_1) is much lower than the peak flow velocity (V_2) and can be frequently ignored, leaving a **simplified Bernoulli equation**:

$$\Delta P = 4V^2$$

The simplified Bernoulli equation is unreliable

a. when V_1 is > 1 m/s, which occurs in serial lesions (subvalvular and valvular stenoses) and mixed stenosis with regurgitation.

b. when viscous resistance becomes significant in the evaluation of long stenoses (e.g., coarctation or a tunnel-like ventricular septal defect).

c. when the inertial term (flow acceleration) is not negligible (flow through normal valves).

It is important to realize that in aortic stenosis the Bernoulli equation represents the **maximal instantaneous gradient** across the valve, which is always higher than the customary peak-to-peak gradient measured in the catheterization laboratory since the LV systolic peak and aortic peak pressures do not occur at the same time and therefore are not instantaneous.

The flow within the heart is pulsatile; hence, mean gradients are an important measure and are obtained by integrating the velocity profile over the ejection time. This can be readily obtained with the software available on all modern echocardiography machines by simply tracing the area of the velocity profile. The mean pressure gradient is then derived from the mean velocity data using the Bernoulli equation.

2. Intracardiac pressure measurement

a. Estimated right atrial (RA) pressure can be derived from the size of the IVC and its response to changes in respiration or a sniff (Table 67.7). Using a dilated IVC to assess elevated RA pressures is not accurate in mechanically ventilated patients; however, a small IVC of size < 1.2 cm in a mechanically ventilated patient is 100% specific for an RA pressure < 10 mm Hg.

b. Pulmonary artery systolic pressure (PASP) is estimated from the TR peak velocity. Provided that there is no tricuspid valve obstruction, peak

TABLE 67.7 Estimation of Right Atrial Pressure

IVC	Change with respiration/sniff	Est. RA pressure (mm Hg)
Normal (< 1.7 cm)	Decrease > 50%	0–5
Dilated (> 1.7 cm)	Decrease > 50%	6–10
Dilated (> 1.7 cm)	Decrease < 50%	10–15
Dilated (> 1.7 cm)	No change	> 15

IVC, inferior vena cava; RA, right atrial.

TR velocity will depend on the pressure gradient between the right ventricle and the right atrium [difference between peak right ventricular systolic pressure (RVSP) and RA pressure]. Therefore, estimated RVSP is equal to this pressure difference, determined from the peak TR velocity, plus the estimated RA pressure (Table 60.7). If there is no obstruction across the pulmonic valve, the RVSP will be similar to the **PASP**:

$$\textbf{PASP} = 4 \times (\text{peak TR velocity})^2 + \text{estimated RA pressure}$$

c. Pulmonary artery diastolic pressure (PADP). Pulmonary regurgitation represents the pressure difference between the pulmonary artery (PA) and the right ventricle at end-systole. Hence, the end pulmonary regurgitation velocity can be utilized to measure the end-diastolic pressure difference between the PA and the right ventricle. The right ventricular end-diastolic pressure should be similar to the RA pressure; therefore, addition of estimated RA pressure to the end-diastolic pressure difference between the PA and the right ventricle will estimate the PADP:

$$\textbf{PADP} = 4 \times (\text{end pulmonary regurgitant velocity})^2 + \text{estimated RA pressure}$$

d. Estimated left atrial pressure (LAP) or left ventricular end-diastolic pressure (LVEDP). Provided that there is no mitral stenosis, LVEDP and LAP should be the same. This important measure of LV diastolic function can be estimated by several methods.

(1) Deceleration time (DT) of mitral inflow. A DT of < 150 milliseconds is strongly suggestive of an elevated LVEDP/LAP. In very young patients, a DT < 150 milliseconds may be normal. This results from a rapid equalization of pressures secondary to vigorous early diastolic relaxation and is not caused by an elevated LAP.

(2) Difference between pulmonary venous atrial duration and mitral atrial duration. Normally, mitral A wave duration is greater than pulmonary venous atrial reversal (Ar) duration. When LVEDP is increased, the velocity and duration of the mitral A wave decreased, whereas pulmonary vein Ar velocity and duration increased. The difference between the duration of the Ar wave and the mitral A wave correlates with LVEDP. An Ar-A duration of > 50 milliseconds is specific for an elevated LVEDP > 20 mm Hg. This is reliable in patients with reduced EF but not in patients with normal EF. The primary limitation with this method is the difficulty in accurately measuring the duration of Ar.

(3) Combined mitral inflow/CMM index (**E**/V_p ratio). This index has been demonstrated to correlate with LAP/LVEDP, especially when these filling pressures are elevated. A ratio of > 2 is suggestive of elevated filling

pressures. In patients with normal EFs, especially with small ventricles and hyperdynamic function, the flow propagation velocities are not accurate.

(4) **Combined mitral inflow/TDI index** (E/E′ ratio). This index has been shown to be a semiquantitative measure of LVEDP. A ratio of > 10 (using the lateral annulus) or > 15 (using the septal annulus) correlates with a wedge pressure of > 20 mm Hg. A ratio of < 8 (using the lateral annulus) correlates well with normal filling pressures. For values that fall in between these two limits, the clinician should look at all the other information provided by echocardiography such as left atrial size and pulmonary venous Doppler to assess whether filling pressures are elevated.

3. **d*P*/d*t*.** This index of LV contractility is the rate of pressure increase during isovolumic contraction and is traditionally obtained using invasive pressure transducers. It can be estimated from the CW Doppler of the MR jet. During isovolumic contraction, there is no change in LAP; therefore, MR velocity changes reflect d*P*/d*t*, with more rapid increases in MR velocity being associated with increased contractility. The pressure change between 1 m/s and 3 m/s = 4 ($V_2^2 - V_1^2$) = 32 mm Hg. The time it takes the ventricle to accelerate an MR jet velocity from 1 m/s to 3 m/s is measured and then the d*P*/d*t* is calculated as follows:

$$dP/dt = 32 \text{ mm Hg/time (in seconds)}$$

This has been demonstrated to correlate well with invasively measured d*P*/d*t*. It is considered normal when the calculated value is > 1,200 mm Hg/s.

4. **Continuity equation** is an application of the principle of conservation of mass, which states that flow across a conduit of varying diameter is equal at all points. This equation is especially useful in quantifying a stenotic aortic valve area (AVA) that cannot be accurately measured using planimetry from the transthoracic window. Flow at any point in the heart is the product of the cross-sectional area (CSA) and the flow velocity. As flow velocity varies during ejection in a pulsatile system, individual velocities must be integrated to measure total volume of flow (velocity time integral, VTI). This is determined by tracing the spectral Doppler profile, using standard measurement software built into all echocardiography machines.

$$\textbf{Flow at any point} = \textbf{CSA} \times \textbf{VTI}$$

Based on the continuity equation, flow through the LVOT must be equal to flow through the aortic valve; therefore, AVA can be calculated following these steps:

Flow across the LVOT = flow across the aortic valve

$$\text{Area}_{\text{LVOT}} \times \text{VTI}_{\text{LVOT}} = \text{area}_{\text{aortic valve}} \times \text{VTI}_{\text{aortic valve}}$$

$$\text{Area}_{\text{aortic valve}} = \text{area}_{\text{LVOT}} \times \text{VTI}_{\text{LVOT}}/\text{VTI}_{\text{aortic valve}}$$

$$\text{Area}_{\text{aortic valve}} = (\text{diameter}_{\text{LVOT}}/2)^2 \times \pi \times \text{VTI}_{\text{LVOT}}/\text{VTI}_{\text{aortic valve}}$$

$$\textbf{Area}_{\textbf{aortic valve}} = (\textbf{diameter}_{\textbf{LVOT}})^2 \times \textbf{0.785} \times \textbf{VTI}_{\textbf{LVOT}}/\textbf{VTI}_{\textbf{aortic valve}}$$

The assumption is that the LVOT cross-section is a circle. The greatest source of error in this equation is in the measurement of the LVOT diameter because the value is squared, resulting in magnification of any initial measurement error. The appropriate place to measure the LVOT can be difficult to define accurately in some calcified valves. The **dimensionless index** (DI) is the ratio of the VTI of LVOT to the VTI of aortic valve, and it is preferable to use this to assess aortic

stenosis when accurate measurement of the LVOT diameter is not possible or in those patients with history of previous aortic valve replacement. A DI < 0.25 suggests severe aortic stenosis.

$$\mathbf{DI = VTI_{LVOT}/VTI_{aortic\ valve}}$$

Of note, the flow across the LVOT per beat is the SV, which can thus be calculated from the product of the LVOT diameter and flow velocity (VTI_{LVOT})

$$\mathbf{SV = (diameter_{LVOT})^2 \times 0.785 \times VTI_{LVOT}}$$

5. **Volumetric method to assess regurgitant volume/regurgitant fraction.** This is based on the conservation of flow, with total flow across a regurgitant valve being equal to the sum of the forward flow and the regurgitant flow. For example, for MR:

   Total transmitral flow volume = forward flow volume (LVOT flow) + regurgitant volume

   (LVOT flow can be assumed to be the same as the forward flow provided there is no AR.)

   Regurgitant volume = mitral forward flow – LVOT flow

$$\mathbf{Regurgitant\ volume = (diameter_{mitral}{}^2 \times 0.785\ VTI_{mitral}) - (diameter_{LVOT}{}^2 \times 0.785 \times VTI_{LVOT})}$$

$$\mathbf{Regurgitant\ fraction = regurgitant\ volume/total\ mitral\ flow}$$

   Because of the multiple assumptions and calculations performed, this method is prone to error and is rarely used clinically.

6. **The PISA** method is another application of the principle of conservation of mass. It is based on the phenomenon that flow accelerates proximal to a narrowed orifice. This is illustrated by the acceleration of water in a bathtub before it enters the drain pipe. Using color Doppler, as flow accelerates, its velocity may exceed the Nyquist limit which results in color reversal because of aliasing. This is seen as a series of colored ("isovelocity") hemispheres with color flow imaging, with the velocity of flow at the surface of this hemisphere being the aliasing velocity (Nyquist limit) of color flow in that direction. Decreasing the aliasing velocity will increase the size of the hemisphere, as the velocity at which color changes is reduced. In keeping with conservation of mass, blood flow at the surface of this hemisphere is the same as flow through the regurgitant orifice, and this is the basis of using the PISA method to estimate the regurgitant orifice area (ROA) of a valve. PISA has been most extensively used to estimate the mitral ROA to quantify MR.

   Flow at surface of hemisphere = flow through regurgitant orifice

   Surface area of hemisphere × velocity at hemisphere = ROA × peak velocity of regurgitation [using continuous wave Doppler (CW) through the mitral valve]

$$2 \times \pi\ (\text{radius})^2 \times \text{aliasing velocity} = \text{ROA} \times \text{peak MR velocity}$$

$$\mathbf{ROA = 2 \times \pi\ (radius)^2 \times aliasing\ velocity/MR_{CW}\ peak\ velocity}$$

   Therefore, the radius of the PISA hemisphere, the aliasing velocity, and the peak mitral regurgitation (MR) velocity are the measurements needed for calculating ROA. The greatest source of error is in defining the precise location of the ROA, so as to accurately calculate the radius.

This method can also be used to measure MVA in mitral stenosis (where forward flow convergence is seen and measured) and the aortic ROA in AR, although it may be difficult to obtain satisfactory visualization of the aortic PISA for quantification from the apical long-axis view (best view to appropriately line up AR jet with the Doppler). When the jet is eccentric, and a full hemisphere is not visible, an angle correction should be considered. The PISA equation for MR can be simplified if the aliasing velocity is set to 40 cm/s and it is assumed that peak MR velocity will be 5 m/s (equates to a normal LV-to-LA pressure gradient of 100 mm Hg). Using these two constants, the PISA equation is simplified to

$$\textbf{ROA} = (\textbf{radius})^2/2$$

Peak MR velocity will increase or decrease depending on the changes in LV systolic pressure and LAP, and it cannot always be assumed to be 5 m/s. However, this method is useful for semiquantification and rapid assessment. Regurgitant volume can be calculated as follows:

$$\textbf{Regurgitant volume} = \textbf{ROA} \times \textbf{VTI}_{\textbf{MRjet}}$$

7. Pressure half-time ($P\frac{1}{2}$) is used to estimate the MVA, as the time for the pressure to fall by half across a stenotic valve is proportional to the degree of stenosis. It is the time interval for the peak pressure gradient to fall by half. Using the Bernoulli equation to convert pressure to velocity, there is a constant relationship between peak velocity and the velocity at $P\frac{1}{2}$.

Pressure at half the peak pressure = 1/2 peak pressure

$$4 \times (V\tfrac{1}{2})^2 = \tfrac{1}{2}(4 \times V^2_{max}) \rightarrow V\tfrac{1}{2} = V_{max} \div \sqrt{2}$$

In addition, the $P\frac{1}{2}$ has a constant relationship with the deceleration time (DT) of the early mitral filling wave, and it is usually estimated from the following:

$$P\tfrac{1}{2} = 0.29 \times \text{DT}$$

Hence, $P\frac{1}{2}$ can be easily measured by using the DT or by simply measuring the time interval from peak to $\frac{1}{2}$ (which is determined from the V_{max}). Most echocardiographic measurement software packages automatically calculate $P\frac{1}{2}$ when the slope of the CW Doppler of the mitral inflow jet is measured. For mitral stenosis, an empirical constant has been validated to correlate $P\frac{1}{2}$ and MVA:

$$\textbf{MVA} = 220/P\tfrac{1}{2}$$

This has only been validated for native valves and will overestimate valve areas for prosthetic valves. The other primary use of $P\frac{1}{2}$ is to help quantify AR. The $P\frac{1}{2}$ of the AR Doppler velocity jet becomes shorter with worsening AR, as the more severe the AR, the more rapidly the pressures in the aorta and the left ventricle equilibrate. A $P\frac{1}{2} < 250$ milliseconds suggests a severe AR. There are many limitations with this, including the fact that $P\frac{1}{2}$ is affected by aortic and LV compliance and by a change in systemic vascular resistance.

VII. TECHNICAL ASPECTS AND ADVANCED IMAGE ACQUISITION

A. Machine settings. To obtain the best images and accurate Doppler information, it is important to optimize the machine settings during different parts of the examination (Tables 66.5 and 66.6).

1. **Time gain compensation.** These controls differentially amplify the echo signals returning from different depths to compensate for attenuation of the ultrasound beam with increasing distance from the transducer. This function is useful with

higher frequency transducers, as they are associated with more attenuation at greater depths.

2. **Depth.** Start with the greatest depth to get an overview and then decrease the depth to include all of the target structure. A depth of 16 cm is usually adequate for the apical window and 12 cm for parasternal imaging. Increasing the depth decreases the frame rate, reducing temporal resolution.
3. **Transmit gain.** This adjusts the displayed amplitude (power) of all received signals and, therefore, affects the brightness of echoes displayed. Setting the power too low results in inadequate returning signals and poor image quality, whereas setting it too high results in image whiteout.
4. **Compress.** The compress setting is also known as a **dynamic range**. It converts the range of returning echo intensities, which may vary a billion-fold in intensity, into 100 to 200 visual shades of brightness or the "gray scale." Increasing the compress will "soften" the image and allow identification of lower level signals. Decreasing the compress results in the production of high-quality contrast images such that weaker signals are eliminated, noise is reduced, and the strongest echo signals are enhanced. Therefore, the compress/dynamic range is decreased when image quality is poor.
5. **Focus (or position).** The focal zone of the transducer indicates the region of the image at which the ultrasound beam is narrowest, and hence where spatial resolution is maximal. Therefore, it is important to reposition the focus to the area of greatest attention/importance, especially those in the near field. When adjusted proximally, however, distal structures may appear blurred as the ultrasound beams scatter.
6. **Persistence.** Persistence is the temporal averaging of the latest frame with the previous frames to produce a smooth or less noisy display. Fast-moving cardiac structures (e.g., valve leaflets) may appear blurred if the persistence is set above low.

B. Imaging artifacts

1. **Acoustic shadowing.** Highly reflective structures block transmission of ultrasound to distal structures, causing poor imaging of these far-field structures. For instance, a mechanical mitral prosthesis prevents good visualization of the left atrium from the apical window.
2. **Reverberation.** This occurs when multiple linear echo signals are generated from a back and forth reflection between two strong reflectors of the ultrasound signal, before the signal returns to the transducer. These appear as multiple parallel irregular dense lines extending from the structure into the far field (e.g., linear echodensity in the ascending aorta in the PLAX view simulating a dissection flap, which is a reverberation from a more anteriorly lying structure, such as a rib). Reverberation artifacts will be present at a multiple of the distance between the two strong reflectors—usually at twice the distance between the strong reflectors. Careful analysis of the artifact in multiple views and with color Doppler should be performed. Color flow signals will be seen to pass through the artifact.
3. **Refraction.** Refraction of the ultrasound beam as it passes through a tissue layer can result in a side-by-side double image. This artifact is often seen in PSAX views of the aortic valve where the image appears to show two aortic valves overlapping.
4. **Beam width artifact.** Ultrasound beams are 3D and are reflected from 3D structures, but they are displayed in a 2D tomographic plane. Strong reflectors at the edge of a central beam, especially outside the narrow proximal focal zone, can be superimposed on a structure in the central zone with the resulting appearance of a structure within the image, that is, outside the 2D tomographic plane (e.g., an aortic valve in the left atrium in the A4C view).
5. **Range ambiguity.** Echo signals from earlier pulse cycles reach the transducer on the next receiving cycle because of re-reflection, resulting in deep structures that

appear closer to the transducer than their actual location, and are manifested as the appearance of an anatomically unexpected echo. This can be confirmed by the disappearance of the artifact when the depth setting is changed.

6. **Side lobe artifacts.** In addition to the central beam, transducers produce side lobes 10° to 30° off axis. All echoes returning from structures in these peripheral beams are displayed, as if they arose from targets within the main beam. Therefore, strong reflectors may be imaged by these low-intensity side lobes and displayed in an erroneous position on the screen. This is a major source of "clutter" in cardiac cavities. Harmonic echoes have much lower intensity side lobes, with a resulting reduction in side lobe artifacts in the image.

C. Factors affecting color Doppler image. Many factors affect spectral Doppler and color flow Doppler, and it is important to consider these. They can be broadly divided into three groups: machine settings, imaging factors, and hemodynamic factors (see Table 67.8 for tips to optimize Doppler settings).

TABLE 67.8 Tips for the Transthoracic Doppler Examination

1. Doppler (all modalities) is very **angle-dependent**—angle between the ultrasound beam and the blood flow jet of interest should be < 20°. In order to achieve this off-axis views are often required.

PW and CW Doppler

2. Shifting the **Doppler baseline** up or down can double the maximal velocity detected (still < 2 m/s) for PW.
3. Increasing the **depth** decreases the Nyquist limit and reduces the maximal velocity that can be measured with PW.
4. Recheck high-velocity jets with the **Pedoff (CW)** probe to confirm peak velocity (include right upper sternal border positions when trying to obtain peak aortic stenosis velocity).
5. Start with high-**gain setting** and reduce until noise and clutter are adequately suppressed.
6. Set **wall filter** to low to avoid overestimation of low velocities.
7. Decreasing the **compress** enhances the edges of the spectral envelope, increasing it enhances the various velocities displayed within the Doppler envelope.
8. Initially set **"reject"** at low (20–40%) to allow the display of a wide range of signals, then increase to remove signals that obscure the image (i.e., to reduce noise).
9. Adjust **gate width**—1–2 mm for mitral inflow and LVOT, 3–4 mm for pulmonary venous flow, and 5–10 for Doppler tissue imaging.

Color flow Doppler

10. **Narrow** the sector and minimize the **depth** to maximize color resolution (increase frame rate).
11. Spatial resolution is higher **axial** to the beam than lateral.
12. Higher **transducer frequencies** result in an increased area of flow disturbance (reduces the Nyquist and increases ability to visualize lower velocities)
13. Adjust **color gain** until just before noise appears in the color.
14. Minimize **wall filters** during analysis of PISA/flow convergence, to avoid overestimating low velocities.

(*Continued*)

TABLE 67.8 Tips for the Transthoracic Doppler Examination (*Continued*)

15. Decreasing the **Nyquist limit** increases the size of any regurgitant jet as lower velocities are detected (normally not color coded at higher Nyquist velocities); therefore, set at 50–60 cm/s initially.
16. Be careful not to miss or underestimate very **eccentric jets** of mitral regurgitation or aortic regurgitation.
17. Remember that **chamber constraint** reduces the size of a jet.

CW, continuous wave; LVOT, left ventricular outflow tract; PISA, proximal isovelocity surface area; PW, pulsed wave.

1. **Machine settings**
   a. **Nyquist limit.** At any given depth, in color Doppler imaging the Nyquist or aliasing velocity (which is related to the PRF) can be adjusted. Typically, it is set to 50 to 60 cm/s. The lowest velocity that is displayed on the color map is related to the Nyquist (minimal displayed velocity = Nyquist × 2/32). Therefore, decreasing the Nyquist increases the lowest velocity displayed, which has the effect of increasing the size of the jet area.
   b. **Transducer frequency.** In color flow imaging, higher transducer frequency reduces the peak velocity (Nyquist limit) that can be measured (see Doppler equation above). Lower Nyquist results in an increased color flow jet area. Therefore, higher frequency transesophageal echocardiography generally produces larger areas of flow disturbance than transthoracic echocardiography. In spectral Doppler imaging, lower frequency transducers can measure higher velocities.
   c. **Depth setting.** Minimizing the depth setting to encompass only the region of interest maximizes the PRF and frame rate.
   d. **Gain.** Adjust the color gain until just before random noise appears in the color. Increased color gain increases the size of color flow disturbance. Two-dimensional gain should be decreased during the color Doppler examination to maximize color flow disturbance because each pixel is assigned to either 2D or color. In PW and CW Doppler, start with a high-gain setting until the desired signal is appreciated. The gain is decreased until noise and clutter are adequately suppressed.
   e. **Baseline.** Used primarily for unwrapping aliased signals. Generally leave it in the middle of the color bar, but it can be adjusted to maximize the velocity that can be displayed with PW or color Doppler. This is also useful for highlighting a specific velocity as in proximal convergence analysis.
   f. **Wall filter.** Excludes low-velocity, high-amplitude signals from myocardial motion. If set too high, it tends to decrease the color flow disturbance. A typical initial setting is 400 Hz. The setting of the wall filter should be minimized during analysis of the proximal flow convergence region to avoid overestimation of low velocities (i.e., set low for PW Doppler and high for CW Doppler).
   g. **Beam width.** Beam width is especially important with PW and CW Doppler. As the ultrasound beam propagates, it spreads out. For example, when sampling pulmonary venous flow with pulse Doppler from the apical view, the sample volume may be at 16-cm depth and the ultrasound beam may be > 1 cm in width. This can lead to the detection of aortic flow, which is displayed as if it arose along the beam axis (from the pulmonary vein) leading to beam width artifact.

h. **Gate length or sample size.** This is the size of the PW Doppler sampling region. It is usually set at 3 to 5 mm. Narrowing the gate focuses the velocity data to a smaller spatial area and can help improve image quality, but it requires very accurate positioning to prevent missing of the appropriate sample area during cardiac motion.

i. **Scale.** Controls the range of Doppler velocities displayed. As the velocity scale increases, the velocity limits increase and the displayed waveform size decreases.

j. **Compress.** In spectral (PW and CW) Doppler, the compress setting adjusts the gray scale, which controls image softness. Decrease the compress to enhance the edges of the spectral envelope. Increase the compress to enhance the various velocities displayed within the Doppler spectrum. Set at 30 dB or higher initially.

k. **Reject.** In spectral Doppler, the reject control removes low-amplitude signals ("noise") from the spectral display. The reject control is initially set at a low level (20% to 40% maximum) to allow the display of a wide range of signals. The reject is then increased to remove signals that obscure the image.

2. **Imaging factors**

a. **Interrogation angle.** Color flow imaging measures only the component of flow that is parallel to the ultrasound beam. This is related to the true flow velocity by the cosine of the angle between the blood flow and the interrogating ultrasound beam. Satisfactory alignment (as parallel to the flow as possible) is vital to record the full and maximal velocity jet with spectral (both PW and CW) Doppler.

b. **Attenuation.** Loss of signal strength caused by too high a transducer frequency for the required depth results in a reduced area of color flow disturbance.

c. **Acoustic shadowing.** Loss of signal strength caused by a proximal reflector of ultrasound (e.g., a mechanical prosthetic valve preventing apical imaging of MR jet in the left atrium).

3. **Hemodynamic factors**

a. **Flow volume.** Increasing regurgitant volume results in an increased area of color flow disturbance, and this is the basis for the common practice of judging the severity of valvular regurgitation by the size of the color jet. However, as outlined in this chapter, many factors affect the size of the color flow jet area. Therefore, it is important to include other factors in the assessment of regurgitation, such as ventricular and atrial sizes, the morphologic appearance of the valve, the width of the color jet at its narrowest point (vena contracta), and, in particular, more quantitative analysis using the proximal flow convergence region (PISA). Several cardiac cycles should be inspected with minor adjustments in the angle of interrogation to ensure that the largest jet is visualized.

b. **Driving pressure.** Increased pressure gradient across a regurgitant orifice results in an increased color flow disturbance in the receiving chamber. Color jet size is closely related to jet momentum, given by flow rate multiplied by jet velocity.

c. **Chamber constraint in eccentric jets.** Impingement of a regurgitant jet against walls of the receiving chamber will decrease the size of the color disturbance. For example, severe but eccentric MR may have a very small area of color flow disturbance because the jet loses momentum to the constraining left atrial wall and appears narrower in a 2D view as it is splayed out over a larger surface area of the wall.

4. **Doppler artifact.** Mirror image artifact can be seen occasionally when the Doppler signal is duplicated on the other side of the baseline.

ACKNOWLEDGMENTS: *The author thanks Drs. Patrick J. Nash, Steven Lin, Guy Armstrong, and Ron Jacob for their contributions to earlier editions of this chapter.*

Transesophageal Echocardiography

I. INDICATIONS. In general, transesophageal echocardiography (TEE) is performed when there is a clinical question for which the information obtained using transthoracic echocardiography (TTE) is insufficient. This may be to better define pathology that has been identified by TTE or to obtain better images when transthoracic images are inadequate. The close proximity of the esophagus to the heart allows for improved visualization of many cardiac structures, particularly those that are posteriorly located. In addition, higher frequency probes can be used, given the shorter distance between the probe and the heart, further enhancing the resolution. However, imaging planes are somewhat constrained by the relative position of the esophagus and heart, and some structures (e.g., prosthetic aortic valve) and certain Doppler measurements may be better assessed by TTE.

Indications for TEE in various conditions and clinical situations are listed in Table 68.1. Very common indications include examination to rule out a cardiac source of embolus, assessment of valves, prosthesis, and intracardiac device for endocarditis or its accompanying complications, such as abscess. The assessment of native and prosthetic valvular function, in terms of degree and mechanism of regurgitation or stenosis, is a frequent indication for TEE. Acoustic shadowing by prosthetic valves, particularly in the mitral position, poses less of a problem for TEE than it does for TTE. Given the increasing prevalence of atrial fibrillation, another frequent indication for TEE is to assess left atrial and left atrial appendage pathology and function, particularly prior to cardioversion. Congenital cardiovascular abnormalities, intracardiac shunts, as well as intracardiac tumors and masses can also be well delineated by TEE. Because of its ability to assess the ascending aorta, arch, and descending aorta, TEE also has an important role in the diagnosis of aortic dissection, aneurysms, and atheroma. In extremely technically difficult/limited transthoracic study such as in postoperative and mechanically ventilated patients, TEE may be used for usual TTE indications such as the assessment of left ventricular function.

TEE is a useful imaging modality in both the operating room and the cardiac catheterization laboratory. In cardiothoracic surgery, TEE is used to assess the mechanism of valvular abnormalities and subsequently evaluate the efficacy of valve repair or replacement. TEE can be used to guide the location of the aortic cross-clamp so that segments with severe atheromatous involvement can be avoided, thereby reducing the risk of embolization. In addition, TEE can provide an assessment of left ventricular function and regional wall motion. As newer transcatheter approaches have become common, including percutaneous valve procedures, closure of paraprosthetic leaks, atrial septal defects, ventricular septal defects, and patent foramen ovale as well as electrophysiological procedures, TEE has been increasingly utilized to help guide catheter position and placement of percutaneous valve or occluding device and evaluate the success and complications of the procedure.

II. CONTRAINDICATIONS

A. There are few **absolute** contraindications to the performance of TEE (Table 68.2). These include the **presence of pharyngeal or esophageal obstruction, active upper gastrointestinal bleeding, recent esophageal or gastric surgery, and suspected or**

TABLE 68.1 Indications for Transesophageal Echocardiography in Various Conditions and Clinical Situations

Condition	Indication
Infective endocarditis	Patients with at least moderate pretest probability such as *Staphylococcus* bacteremia, fungemia, prosthetic valves, or intracardiac device
	Detection of complications of endocarditis: abscesses and fistula
Cardioembolic source	Identification of left atrial and left atrial appendage thrombus or spontaneous echo contrast
	Identification of patent foramen ovale, atrial septal defect, or atrial septal aneurysm
	Identification of aortic atheroma
	Evaluation of mitral and aortic valve for vegetation, tumors, and valve strand
Valvular heart disease	Evaluation of mechanism and severity of mitral regurgitation
	Characterization of valvular pathology such as aortic morphology
Prosthetic valves	Evaluation of suspected prosthetic dysfunction (stenosis, thrombosis, or regurgitation)
Atrial fibrillation/flutter	Assessment of left atrial and left atrial appendage thrombus prior to cardioversion (e.g., if atrial fibrillation > 48 h) or ablation
	Follow-up for resolution of thrombus after anticoagulation prior to cardioversion or ablation
Aortic disease	Evaluation for suspected acute aortic pathology: dissection, aortic trauma, and intramural hematoma
	Characterization of aortic aneurysm and atheroma
Interventional procedures	Guiding performance of interventional cardiac procedures (e.g., percutaneous valve procedure, balloon valvuloplasty, closure of paraprosthetic leak, ASD, VSD, or PFO)
Intraoperative	Assessment of valve repair/replacement and evaluation of systolic function
Intracardiac masses	Detection of characterized masses such as tumors and thrombus
Critical care	Assessment of suspected papillary muscle rupture
	Assessment of mechanical complications of acute myocardial infarction or mural thrombus
	Evaluation of unexplained hypotension, especially in the ICU
	Assessment of early postoperative bleeding, which may result in localized accumulation of blood clots (especially posteriorly)
Congenital heart disease	Identification of site of origin and initial course of coronary arteries
	Detection of intracardiac shunts

ASD, atrial septal defect; VSD, ventricular septal defect; PFO, patent foramen ovale; ICU, intensive care unit.

TABLE 68.2 Transesophageal Echocardiography Contraindications

Absolute
Esophageal or pharyngeal obstruction
Suspected or known perforated viscus
Gastrointestinal bleeding that has not been evaluated
Instability of cervical vertebrae
Relative
Esophageal varices or diverticula
Cervical arthritis
Oropharyngeal distortion
Bleeding diathesis or overanticoagulation
Uncooperative patient

known perforated viscus. If there is instability of the cervical vertebrae, then the examination cannot be performed.

B. **Relative** contraindications include the **presence of esophageal varices** and **suspected esophageal diverticulum**. In these cases, it is prudent to obtain gastrointestinal evaluation before proceeding, if the study must be performed. Severe cervical arthritis, in which patients may have difficulty with neck flexion, may make it difficult to pass the probe. Oropharyngeal pathology, anatomic distortion, or extreme muscle weakness can likewise make it difficult to proceed with the examination.

C. **Severe cardiopulmonary disease** is not a contraindication to evaluation by TEE (on the contrary, TEE can often provide critical information when used in these patients), but the operator must be particularly careful to minimize any stress on the patient. This is particularly true in **suspected aortic dissection**, where any sudden increase in blood pressure caused by patient discomfort could result in extension of the dissection. In cases where there is **respiratory instability**, endotracheal intubation with assisted ventilation should be considered prior to the procedure. Patients who are **hypotensive** may not be able to receive sedative agents, as these agents could lead to further hemodynamic compromise. In such patients, the examination may have to be performed with topical anesthesia alone. This is obviously much more difficult for the patient, and TEE should be done only if critical information is not obtainable by other methods.

D. Given the invasive nature of the procedure, prudence must be observed in patients who are prone to **bleeding**. The procedure is commonly performed on patients who are anticoagulated, such as in those with atrial arrhythmias prior to cardioversion. However, there is increased risk in those who are overanticoagulated. Although no set guidelines exist, it would seem advisable to **delay the examination if possible in patients with an international normalized ratio > 5 or a partial thromboplastin time > 100 seconds. Thrombocytopenia** may also increase the risk, particularly with platelet counts **< 50,000/mm^3**. TEE can still be performed if needed, as the absolute risk remains low, but meticulous attention must be given to nontraumatic esophageal intubation.

E. **Esophageal infections**, such as those that occur in the context of human immunodeficiency virus (HIV), do not necessarily represent contraindications to the procedure. **Patient discomfort** caused by the presence of the probe in the esophagus may preclude the examination. Universal precautions should be followed (as they should for any patient). The standard disinfectants used to clean the probe will inactivate HIV.

F. A patient who is very uncooperative is at significant risk for complications from the procedure. In such a case, consideration should be given to aborting the TEE or to increase the level of sedation and prophylactic endotracheal intubation if required.

III. PERSONNEL. The American Society of Echocardiography has proposed the following guidelines for operators who wish to perform TEE: as background, attainment of at least level 2 experience in transthoracic echocardiogram; a minimum of 25 esophageal intubations under guidance; and a minimum of 50 supervised TEE examinations during training. Furthermore, operators should perform a minimum of 25 to 50 TEE examinations yearly to maintain competency.

The presence of a skilled assistant is invaluable during the procedure. The assistant should be either a sonographer or a registered nurse. The role of the assistant is to monitor vital signs during the procedure, ensure proper suctioning of oropharyngeal secretions, and administer medications.

IV. EQUIPMENT. Necessary equipment is listed in Table 68.3.

V. THE TRANSESOPHAGEAL PROBE. The probe is a modification of the standard gastroscope, with transducers in place of fiber optics. The conventional rotary controls with inner and outer dials are present. The inner dial typically guides anteflexion and retroflexion, whereas the outer dial controls medial and lateral movement of the tip. A locking mechanism is present, which must not be in effect when the probe is advanced or withdrawn, as esophageal trauma may result. The multiplane probe also has a lever control to guide rotation. Biplane probes are no longer in common use, as they require switching between the transverse and longitudinal planes by a control switch on the echo machine. Advancement and withdrawal of the probe, rotation of the probe about its long axis, and the manipulations available using the above rotary controls constitute the means by which specific images can be obtained (Fig. 68.1).

TABLE 68.3 Equipment for Transesophageal Echocardiograph

1. Echo machine and probe (calibrate prior to intubation)
2. Sphygmomanometer
3. ECG rhythm monitor
4. Pulse oximeter
5. Supplemental oxygen
6. Wall suction with Yankauer
7. Intravenous lines and tubing
8. Topical anesthetic agents
9. Sedative medications
10. Bite block
11. Gloves and goggles
12. Emergency equipment
    - **a.** Drugs (e.g., atropine, epinephrine, naloxone, flumazenil, and lidocaine)
    - **b.** Defibrillator
    - **c.** Intubation supplies

ECG, electrocardiogram.

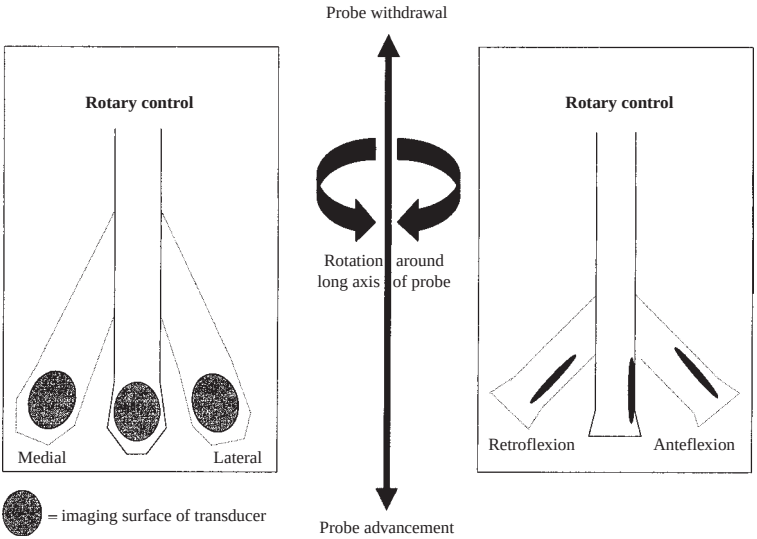

FIGURE 68.1 Specific images can be obtained by advancement and withdrawal of the probe, by rotation of the probe about its long axis, and by the manipulations that are possible using rotary controls.

VI. PATIENT PREPARATION (Table 68.4). The patient should have had nothing by mouth (NPO) for at least 4 to 6 hours before the procedure. Water is allowed up to 2 hours before the test. The clinician can rule out possible contraindications by asking for a history of odynophagia or dysphagia. It is important to be aware of any history of radiation therapy to the mediastinum or cervical region that may have resulted in stricture formation.

The extent of previous workup for any history of gastrointestinal bleeding must be reviewed. The clinician should review recent laboratory studies, paying particular attention to platelet count, hemoglobin level, and coagulation profile. Appropriate inquiries should be made with regard to allergies and former tolerance of sedative medications. The clinician should ensure that the patient understands the procedure, including risks and benefits, and that proper informed consent is obtained and documented before proceeding.

TABLE 68.4 Preparation for Transesophageal Echocardiography

Patient must have had nothing by mouth (NPO) for at least 4 h prior to the procedure
Assess for possible contraindications:
History of odynophagia or dysphagia
History of mediastinal or cervical radiation that might have resulted in stricture formation
History of and workup for gastrointestinal bleeding
Allergies to and previous tolerance of sedative medications
Patient understanding of procedure and indications
Informed consent of patient

VII. STEP-BY-STEP GUIDE TO THE EXAMINATION

A. The patient's **dentures** should be removed.

B. **An intravenous (IV) line** should be inserted to allow for administration of medications and saline contrast for study.

C. The American Heart Association does not recommend **antibiotic prophylaxis** for patients undergoing endoscopic procedures. The reported incidence of transient bacteremia with endoscopy is no higher than the contamination rates reported with blood cultures.

D. A **blood pressure cuff** should be placed on the patient's arm.

E. **Electrocardiographic leads** should be applied and connected to the telemetry monitor.

F. A **pulse oximeter** should be applied to the patient's finger or ear.

G. A **nasal cannula** should be used so that supplemental oxygen can be given as needed.

H. While sitting up, the patient should be asked to gargle **viscous 2% lidocaine** for 1 minute and then swallow it for topical anesthesia. **Lidocaine (xylocaine) spray (4%) or Cetacaine spray (10%)** is then sprayed on to the posterior tongue and upper pharynx. These procedures normally suppress the **gag reflex**, but if necessary, this can be verified using a tongue depressor or gloved finger; additional **topical anesthesia** is then applied until the reflex is dulled. By visualizing the area being sprayed, inadvertent spraying of the vocal cord and resultant laryngospasm can be avoided. Methemoglobinemia has been reported with the use of benzocaine-containing product (e.g., Cetacaine), which is usually manifested as central cyanosis and desaturation and can be treated with supplemental oxygen and methylene blue. Some operators advocate the use of drying agents to minimize oropharyngeal secretions (e.g., glycopyrrolate). We generally have not found a need for use of such agents, which can cause an increase in heart rate.

I. Have the patient lie down on the left side (left lateral decubitus position), facing the echo machine (alternatively, the patient can lie on the right side, with the machine on the right), with neck flexed. TEE can be performed with the patient sitting, but is easier in the lateral position.

J. **Midazolam**, a benzodiazepine, is the preferred agent for sedation, having the benefit of a short half-life. It also produces an antegrade amnesic effect and has anxiolytic properties. Typically, administer IV doses of 0.5 to 1 mg every 3 to 5 minutes until adequate sedation is achieved. The goal is to reduce anxiety without compromising respiratory drive and while maintaining the patient's ability to follow simple commands, such as swallowing when necessary. Check pulse oximetry and blood pressure before each dose. **Fentanyl**, a short-acting opioid analgesic, can be used for sedation (typically 25 μg IV per dose) in conjunction with midazolam and may be better tolerated in patients with poor left ventricular function or renal impairment. An alternative sedative is **meperidine**, which is typically given in 12.5 to 25 mg IV doses. Meperidine possesses an analgesic effect and helps to suppress the gag reflex as well. Again, **check vital signs before and after each dose**. Additional doses of these sedatives and anxiolytics may be administered during the procedure if necessary. Sedation can lead to potential respiratory suppression; therefore, a benzodiazepine antagonist (e.g., flumazenil 0.2 to 0.6 mg IV) and an opiate antagonist (e.g., naloxone, increments of 0.1 to 0.2 mg IV doses) should be available if required.

K. With adequate sedation and topical anesthesia (diminution of gag reflex), **begin probe insertion**. There are two approaches that are generally used.

1. The first is the **digital technique**, which is especially useful with the larger multiplane probe. With this method, the bite guard is inserted onto the shaft of the probe such that after esophageal intubation the bite guard can be moved into place. The distal end of the probe is lubricated. The imaging surface of the transducer is placed toward the tongue. The tip of the transducer is placed under the index finger, and it is slowly guided downward and posterior to the hypopharynx. At this point the patient is asked to swallow, and gentle pressure is applied with the other hand to guide the probe down. Swallowing results in relaxation of the upper

esophageal sphincter. If resistance is met, stop, let the patient relax, and reattempt or redirect as needed. Using the finger as a guide will help center the probe in the region of the hypopharynx over the esophagus and avoid the lateral recesses.

2. An **alternative method is to use the rotary controls on the TEE probe** to guide the intubation. The bite guard is inserted first. The probe is inserted through the bite guard, and gentle anteflexion is applied as the probe is passed over the back of the tongue. The probe is then returned to the neutral position, or with slight retroflexion, as it is passed down into the esophagus. The patient is asked to swallow as the probe is advanced past the upper esophageal sphincter. The operator is still able to guide the probe if needed by insertion of a finger around the side of the bite guard.

   Patients often gag as the probe enters the upper esophagus (even with adequate anesthesia); however, patients generally find it more comfortable once the probe has passed beyond this point (usually at 25 cm, past the level of the carina). The probe should be advanced to approximately 30 to 40 cm (midesophageal level).

   In intubated patients, it is important to **secure the endotracheal tube firmly to one side of the mouth** to prevent dislodgment and inadvertent extubation. Direct visualization with a laryngoscope may be needed. **Sedation** is equally important in these patients, and given the tendency for partially sedated patients to bite on their tubes, a **paralyzing agent** is often required. Intubation in the supine position is not a problem because the airway is protected. Other catheters in the esophagus, such as feeding tubes or nasogastric tubes, often have to be removed prior to the procedure; they may become interposed between the esophagus and the TEE probe, interfering with the images. If left in, these tubes may become dislodged by the TEE probe, and tube position should be reconfirmed after the echocardiographic examination.

   For patients with tracheostomies, some operators will carefully and gently deflate the cuff to facilitate probe insertion.

VIII. IMAGING. TEE technology has undergone much evolution, from the initial monoplane views to the current multiplane views. Monoplane TEE provides for images in the horizontal plane only, perpendicular to the shaft of the endoscope. Longitudinal relationships among cardiac structures are difficult to appreciate. With biplane TEE, the orthogonal longitudinal plane can also be obtained. Both monoplane and biplane systems required additional manipulation to obtain off-axis views, making the examination more difficult and more uncomfortable for the patient. With **multiplane TEE**, the transducer has a single array of crystals that can be rotated 180° around the long axis, producing a continuum of transverse and longitudinal images from a single probe position. This minimizes the probe manipulation necessary to obtain intermediate and off-axis images. Consequently, multiplane TEE has increased sensitivity for the detection of sometimes subtle abnormalities, including vegetations, periprosthetic leaks, left atrial appendage thrombi, and aortic dissection. The development of **real-time three-dimensional (3D) TEE** (see Section **VIII.C**) offers the possibility of assessing cardiac structures volumetrically. It has emerged as a clinically relevant modality by providing relatively high image quality, which may enhance clinical decision making especially in regard to structures with a complex anatomy such as the mitral valve. However, this technology is still evolving, particularly with regard to its value in routine clinical practice.

A. Basic views. The TEE examination tends to be more goal directed than the transthoracic examination, as there may be time constraints imposed by how long the patient can tolerate the esophageal probe. Initial views should focus on the question at hand, but it is still important to perform a comprehensive and thorough examination. Most operators prefer to begin with upper esophageal views before proceeding to transgastric views. The order of views obtained is not important, provided the operator develops a consistent and comprehensive approach.

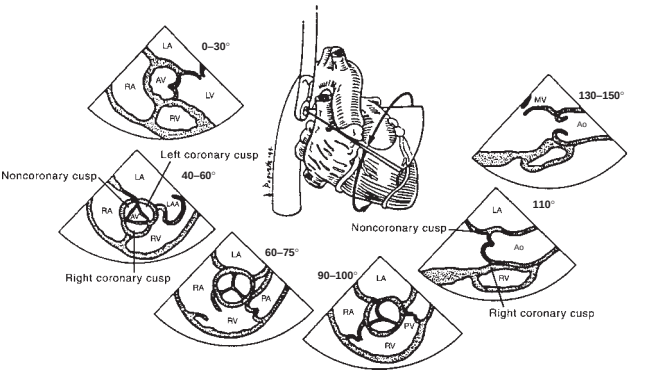

FIGURE 68.2 Schematic representation of selected multiplane transesophageal echocardiography views of the aorta and aortic valve from the upper esophagus. Ao, aorta; AV, atrioventricular; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; PA, pulmonary artery; PV, pulmonary valve; LAA, left atrial appendage; MV, mitral valve. Modified from Roelandt JRTC, Pandian NG, eds. *Multiplane Transesophageal Echocardiography*. New York, NY: Churchill Livingstone; 1996:15–68.

The probe may inadvertently rotate during insertion and may require initial manipulation before starting the examination. The left atrium should be seen at the center of the screen. If the aorta is seen (which is posterior to the esophagus), then the probe must be rotated anteriorly. Slight retroflexion of the probe may be necessary to maintain adequate contact between the probe and the esophagus. Air in the esophagus, which is interposed between the probe and the heart, may affect image quality. This generally lessens as the examination progresses (from ongoing peristaltic activity in the esophagus). Similarly, the presence of a hiatal hernia may compromise image quality.

Views obtained from multiplane TEE are described first. These views are described in terms of degrees of rotation required to obtain particular images. At each transducer location, start array at 0° and rotate to 180° at 5° to 15° increments to obtain a complete sweep. The standard horizontal plane is designated as 0°. At approximately 45°, short-axis views are obtained. Ninety degrees is defined as the longitudinal plane, whereas at around 135°, the true long-axis cardiac views are obtained. At 180°, a mirror image view of the standard horizontal plane is obtained. Given the variable anatomic relationships between structures, the degree of probe manipulation required to obtain the standard views will vary from patient to patient.

1. **Upper esophagus (30 cm)—base of the heart** (Fig. 68.2). With the array at 0°, a five-chamber cross-sectional view of the left atrium, left ventricle, right atrium, right ventricle, and aortic valve is obtained. At 40° to 60°, the three leaflets of the aortic valve become visible (right coronary cusp at the bottom of the screen, noncoronary cusp on the top and to the left, and left coronary cusp on the right). Planimetry of the aortic valve orifice is often possible in this view. Subtle in-and-out movements allow for visualization of the proximal coronaries. The left atrial appendage is also seen in this view (zooming in on the atrial appendage, with subsequent rotation of the array, facilitates inspection for thrombus). At 60° to 100°, the tricuspid valve and right ventricular outflow tract/pulmonic valve become visible. At 120°, long-axis images of the left ventricular outflow tract, aortic valve (noncoronary and right coronary cusps), and proximal ascending aorta are seen. Slight withdrawal of the probe at 110° to 120° permits visualization of the ascending aorta. With the probe withdrawn further into the upper esophagus (Fig. 68.3), the pulmonary artery and its bifurcation can be visualized (from 0° to 45°).

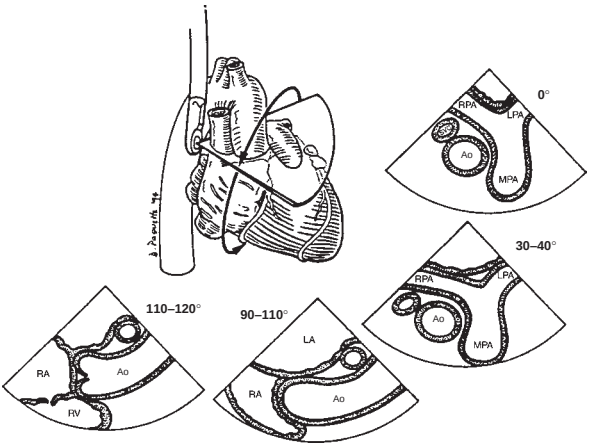

FIGURE 68.3 Schematic of some of the multiplane transesophageal echocardiography views of the aorta and pulmonary artery that can be obtained from the upper esophagus. Ao, aorta; LA, left atrium; LPA, left pulmonary artery; MPA, main pulmonary artery; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena cava. Modified from Roelandt JRTC, Pandian NG, eds. *Multiplane Transesophageal Echocardiography*. New York, NY: Churchill Livingstone; 1996:15–68.

2. **Lower and middle esophagus** (Fig. 68.4A and B). With the array at 0°, a four-chamber view is obtained (some retroflexion of the probe is needed for a true four-chamber view, as with anteflexion one will see portions of the left ventricular outflow tract and aortic valve). This view is similar to an inverted transthoracic apical four-chamber view. With the left atrium and left ventricle kept in the center of the view field, rotation of the array allows for a thorough evaluation of the left-sided structures. Doppler interrogation of mitral inflow is generally performed with the array at 0° to 30°. Skillful maneuvers as the array is rotated to 90° allow for interrogation of both leaflets of the mitral valve, including the specific scallops of the leaflet. Rotation of the array to 90° to 110° reveals the two-chamber view (left atrium/left ventricle), with the anterior and inferior walls of the left ventricle visualized. The left atrial appendage and the left upper pulmonary vein are also seen. Long-axis views of the left ventricular outflow tract, aortic valve (right and noncoronary cusps), and proximal ascending aorta are obtained by rotation to 120° to 140°. The anterior mitral leaflet is particularly well visualized in these views. This complete sweep permits full delineation of the extent of mitral regurgitation.

   Similar views of right-sided structures and the interatrial septum can also be obtained from this position. At 0° (in the four-chamber view as described previously), the septal and anterior leaflets of the tricuspid valve can be seen. The endoscope is then rotated to bring the interatrial septum and the right atrium to the center of view (some withdrawal or advancement of the probe may be necessary to optimize visualization of the interatrial septum). By rotation of the multiplane array, the interatrial septum and fossa ovalis can be thoroughly examined for evidence of a patent foramen ovale or atrial septal defect. Agitated saline contrast can be given intravenously at this time to expose evidence of shunting; asking the patient to perform Valsalva maneuver or to cough can help identify right-to-left shunting. At approximately 100°, the superior vena cava and inferior vena cava can be seen entering the right atrium, and the right atrial appendage

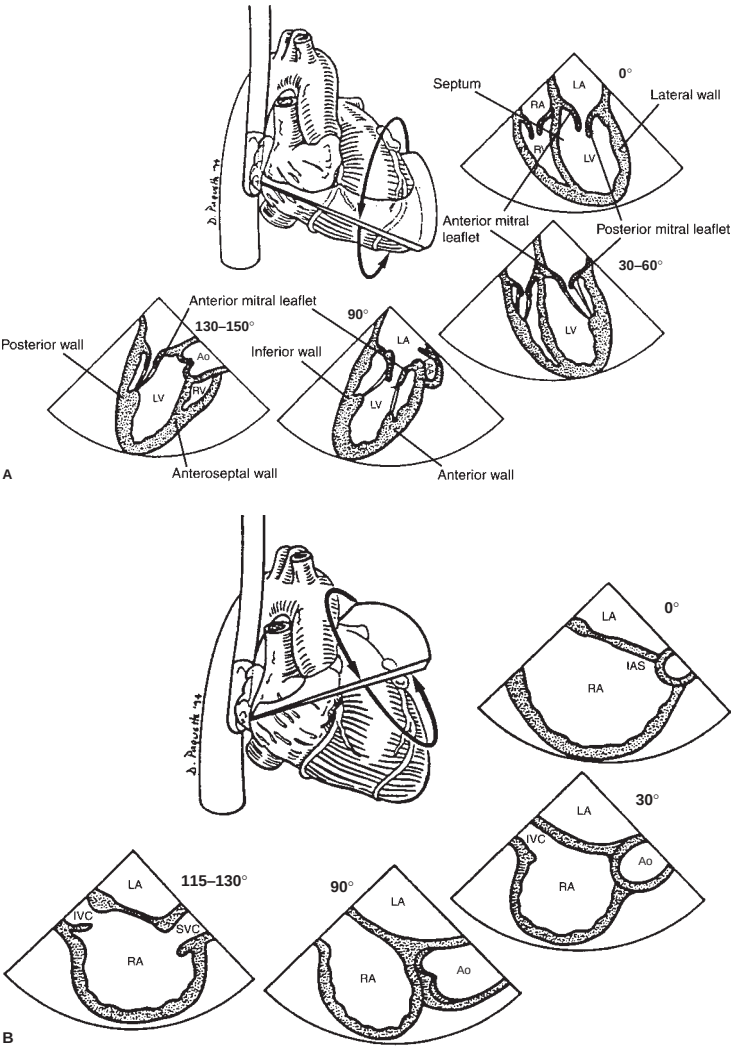

FIGURE 68.4 **A:** Schematic diagram showing some representative sections of the left heart that can be obtained with multiplane transesophageal echocardiography from the lower and middle esophagus. AA, left atrial appendage; Ao, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. Modified from Roelandt JRTC, Pandian NG, eds. *Multiplane Transesophageal Echocardiography*. New York, NY: Churchill Livingstone; 1996:15–68. **B:** Schematic diagram showing representative multiplane transesophageal echocardiography sections of the atria and interatrial septum that can be obtained from the lower middle esophagus. Ao, aorta; IVC, inferior vena cava; LA, left atrium; RA, right atrium; SVC, superior vena cava; IAS, interatrial septum. Modified from Roelandt JRTC, Pandian NG, eds. *Multiplane Transesophageal Echocardiography*. New York, NY: Churchill Livingstone; 1996:15–68.

can also be seen. This is a good view to identify anomalous pulmonary venous drainage into the right atrium or superior vena cava or a sinus venosus atrial septal defect. Further rotation will allow for assessment of the right pulmonary veins.

3. **Transgastric views**
   a. **Proximal** (Fig. 68.5A). These are images obtained from the fundus of the stomach. A cross-sectional view of the left and right ventricles is obtained

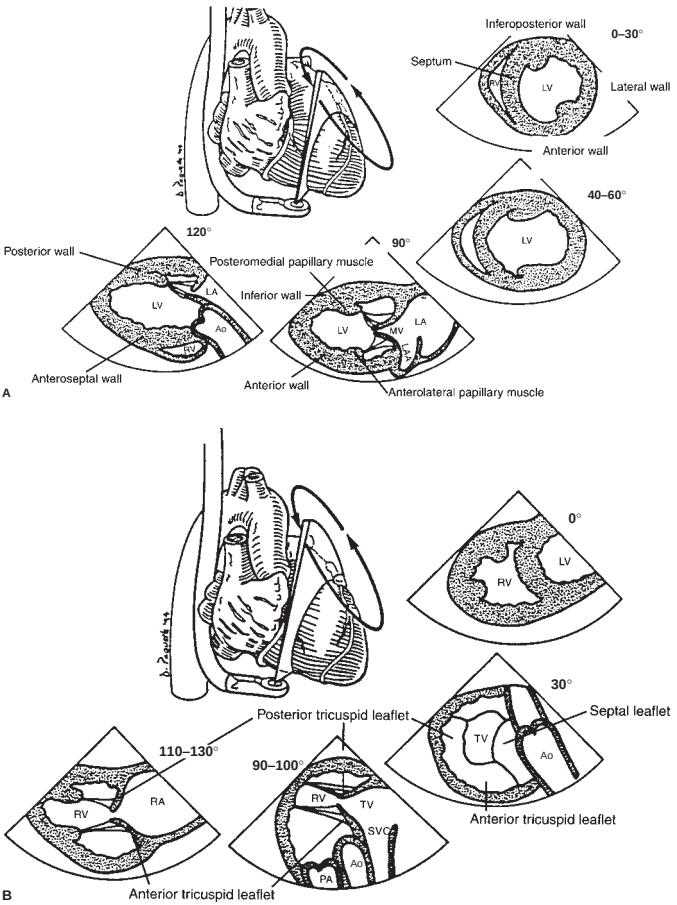

FIGURE 68.5 **A:** Schematic diagram showing representative multiplane transesophageal echocardiography sections of the left heart from the proximal transgastric location. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle; SVC, superior vena cava; LAA, left atrial appendage; MV, mitral valve. Modified from Roelandt JRTC, Pandian NG, eds. *Multiplane Transesophageal Echocardiography*. New York, NY: Churchill Livingstone; 1996:15–68. **B:** Schematic of images from a transgastric, multiplane sweep through the right ventricle. LV, left ventricle; RA, right atrium; RV, right ventricle; TV, tricuspid valve; SVC, superior vena cava; PA, pulmonary artery; Ao, aorta. Modified from Roelandt JRTC, Pandian NG, eds. *Multiplane Transesophageal Echocardiography*. New York, NY: Churchill Livingstone; 1996:15–68.

at 0°. By rotating the shaft of the endoscope to center with the left ventricle in the field of view, serial short-axis ("doughnut") views of the left ventricle can be obtained. Anteflexion of the probe will give rise to basal views, with the mitral and tricuspid valves seen in cross section. With the transducer in a more neutral position, middle and apical short-axis views will be obtained.

At 80° to 100°, a two-chamber view of the left atrium (with appendage) and left ventricle (anterior and inferior walls of the left ventricle, mitral leaflets, and papillary muscles) will be obtained. At ≥ 120°, a long-axis outflow tract view with aortic valve and ascending aorta will be visualized. The anteroseptal and posterior walls of the left ventricle are seen. Depending on the alignment with the transducer, this view may be useful in obtaining velocities across the aortic valve.

Bringing the array back to 0° and rotating the shaft of the endoscope to center the right ventricle in view will allow for interrogation of the right-sided structures (Fig. 68.5B). At 30° to 60°, the three leaflets of the tricuspid valve are visualized (anterior leaflet at the bottom, posterior leaflet on the top, and septal leaflet to the right). At around 70° to 80°, the right ventricular inflow tract view (superior vena cava and tricuspid valve with anterior and posterior leaflets) is obtained. At 90° to 100°, the right ventricular outflow tract and pulmonary valve become visible as well. At 110° to 130°, the two-chamber view of the right ventricle and right atrium can be seen. By rotating to 130° to 150°, the papillary muscles and chordae supporting the tricuspid valve are further delineated.

b. Deep transgastric. The probe is advanced further into the stomach with the tip anteflexed. At 0°, a foreshortened five-chamber view is obtained. This view allows for Doppler interrogation of the aortic valve and left ventricular outflow tract. By rotating the multiplane array, different segments of the left ventricle apex can be visualized in the search for thrombus or aneurysm.

4. Aorta. Counterclockwise rotation of the endoscope brings the aorta into view. Typically, the probe is advanced beyond the diaphragm and then slowly pulled back, following the aorta back to the arch. Rotation of the probe is required to keep the aorta in view in the center of the screen. At the level of the diaphragm, the aorta is posterior to the esophagus. In the midesophagus, the aorta is medial, whereas the ascending aorta and arch lie anterior to the esophagus. At 0°, the aorta is seen as a circular structure. Long-axis images (at 100° to 130°) provide additional information as needed at selected intervals. At the arch, the aorta is curved in front of the esophagus, presenting a sausage-shaped structure with the probe at 0°. Gentle clockwise rotation will follow the arch back to the ascending aorta. The ascending aorta is visualized in the longitudinal planes as discussed with the other views. Multiplane TEE has reduced the so-called blind spot of the ascending aorta (where the trachea is interposed between the esophagus and aorta, an area that poses a problem during horizontal plane imaging).

B. Biplane probe. There are times during which a biplane probe may be used. This is a smaller probe, so it may be beneficial to use in certain cases when there might be difficulty in esophageal intubation with the multiplane probe. By manipulating the probe via rotation about the long axis and using rotary controls, intermediate and off-axis images in addition to the standard transverse and longitudinal views described earlier can be obtained. Through hands-on experience, the operator will come to be familiar with these maneuvers.

C. Three-dimensional probe. The current 3D TEE probes use fully sampled matrix array transducers, allowing a pyramidal volume of data to be acquired. Besides standard two-dimensional imaging modalities, this transducer is able to perform

3D imaging in several modes: live X-plane imaging, live 3D echo, live 3D zoom, triggered full volume, and triggered 3D color. Real-time X-plane imaging allows simultaneous biplane imaging from the same heart beat. Live 3D mode displays real-time 3D images with a small pyramidal segment; 3D zoom mode displays the region of interest with a larger pyramidal segment in real time. Full volume mode acquires wider segment over several cardiac cycles, and color Doppler can also be added in this mode. Three-dimensional TEE is useful for the evaluation of native valves (in particular mitral valve and aortic valve), prosthetic valves, interatrial septum, and left atrial appendage and for the guidance of percutaneous interventional procedures (in particular mitral valve repair, aortic valve implantation, closure of atrial septal defect, and paraprosthetic leaks).

IX. PATIENT RECOVERY. The patient's NPO status should be maintained until the gag reflex has returned. The patient should be instructed to avoid oral intake for at least 1 to 2 hours after the test. When the patient commences oral intake, he or she should initially take a small sip of cold water. If the water does not feel cold in the back of the throat, then some topical anesthetic effect is still present. The patient should wait for another half hour and test the throat again. Until this has dissipated, the patient should avoid any hot drinks so as to avoid scalding. Appropriate precautions should be followed if sedatives were used, as the effects persist for several hours. Patients may have dizziness and orthostatic symptoms for up to several hours and should be instructed to sit or lie down if this occurs. Patients should not drive or operate heavy equipment until the next day.

X. PROBE CARE. Following use, the probe should be cleaned with soap, water, and an enzymatic solution to remove saliva. The nonimmersible parts of the probe, such as the handle and rotary controls, should be cleaned with alcohol. Afterward, the probe should be soaked in a glutaraldehyde solution for a minimum of 20 minutes and a maximum of several hours to eliminate bacteria. The probe should not be soaked in this solution overnight. It can then be rinsed with water and air-dried. The probe should be inspected closely for any tears or perforations.

XI. COMPLICATIONS. In reported series, the incidence of major and minor complications is 2% to 3%, with most being minor complications. Major complications (death, esophageal perforation, significant arrhythmias, congestive heart failure, and aspiration) occur with a frequency of 0.3%, with a reported mortality of < 0.01%. Reported minor complications include transient hypotension, hypertension (particularly with agitation), transient hypoxia, transient bronchospasm, and arrhythmias (such as supraventricular tachycardia, nonsustained ventricular tachycardia, and transient atrioventricular block). Methemoglobinemia has been rarely reported due to the anesthetic spray and should be considered if cyanosis occurs. Other complications of intubation include tracheal intubation, laryngospasm, and vocal cord paralysis. Sore throat is not uncommon after the procedure and may persist for a day. Anaphylaxis and other allergic reactions can occur due to the medications used.

XII. PITFALLS. The improved resolution and anatomic detail provided by TEE, as compared with TTE, is what makes it such a powerful diagnostic tool. However, this can also lead to misinterpretation of normal structures. Trabeculations in the atrial appendage can be mistaken for thrombi, and lipomatous hypertrophy of the interatrial septum can be incorrectly labeled as a mass, as can the eustachian valve. The transverse and oblique sinuses can be mistaken for abscess cavities. Off-axis images may create the appearance of a mass on the aortic valve when one of the cusps is cut obliquely. The lungs can give rise to reverberation artifacts, which can erroneously be diagnosed as dissection flaps (presence in nonanatomic planes, lack of disruption of color Doppler of blood flow, and crossing of

normal anatomy all favor diagnosis of artifact). Abnormal findings should be visualized and verified in several views to ensure that they do not represent imaging artifacts.

These pitfalls are best minimized by the experience of the operator, but variations in anatomy may provide diagnostic dilemmas for even the most skilled echocardiographer.

ACKNOWLDGMENTS: *The authors wish to thank Deepu Nair, MD, for his contributions to a previous edition of this chapter.*

CHAPTER 69

Justin M. Dunn
Brian P. Griffin

Pericardiocentesis

I. INTRODUCTION. Pericardiocentesis is an important therapeutic and diagnostic procedure in cardiology. Most often, it is used to relieve tamponade and identify causes of pericardial effusions. When performed correctly by experienced operators, pericardiocentesis has proven to be both an effective and safe procedure.

II. INDICATIONS

A. Alleviation of cardiac tamponade. Cardiac tamponade is a clinical diagnosis classically characterized by hypotension, tachycardia, distended neck veins, pulsus paradoxus, and distant heart sounds. Echocardiographic data provide confirmatory evidence for this diagnosis and include effusion (regional or circumferential), inferior vena cava plethora, diastolic collapse of the right atrium and right ventricle, and increased respiratory variation of blood flow through the tricuspid and mitral valves. The normal pericardial cavity typically contains 15 to 50 mL of fluid. **The additional volume of fluid required to cause hemodynamic compromise is variable** and is dependent upon several factors, including the patient's volume status, the rapidity of fluid accumulation, and intrathoracic pressure (positive end-expiratory pressure increases intrathoracic pressure, impairing right heart filling and exacerbating tamponade physiology). Therefore, a relatively small but rapidly accumulating effusion can cause tamponade, particularly in the intravascularly depleted patient.

B. Evaluation of and therapy for pericardial effusion

1. **After open heart surgery.** Effusions after open heart surgery are common; rarely, they may be of hemodynamic significance. Data from the Mayo Clinic suggest that the incidence of significant effusion in patients 18 years of age or older up to 30 days after cardiac surgery with cardiopulmonary bypass is 1.5%. The risk of effusion is highest in patients undergoing heart transplant and lowest in patients undergoing coronary artery bypass grafting. Renal failure, immunosuppression, pulmonary thromboembolism, prolonged cardiopulmonary bypass, and high body surface area were all independent risk factors for significant effusion. The contribution of anticoagulation to effusion formation is less established, but it is likely a risk factor as well. It should be noted that approximately **50% of patients who were discharged with a small clinically insignificant pericardial effusion, especially those status post valve surgery, required readmission** approximately 2 weeks after surgery for treatment of tamponade.
2. **Idiopathic.** In patients presenting with large, idiopathic effusions, evaluation of pericardial fluid—including cytologic examination, culture, cell counts, and chemistries—frequently assists in diagnosis. In fact, data suggest that the causes of most effusions can be diagnosed with history, physical examination, laboratory evaluation, and pericardial fluid analysis. Fluid analysis has been shown to be more helpful than pericardial tissue biopsy for culture of viral and bacterial

pathogens, and cytology is positive in 65% to 85% of cases of malignant effusion. Some experts recommend that large pericardial effusions (> 20 mm) be drained if the effusion persists for more than 1 to 3 months. **Up to one-third of patients with large idiopathic pericardial effusions develop cardiac tamponade unexpectedly**.

3. **Malignant.** Malignant pericardial effusions are a rare manifestation of metastatic disease. Fluid cytology is usually positive and can be of value if the primary tumor is unknown. Lung, breast, and hematologic cancers are the most common etiologic factors. Controversy exists regarding the most appropriate management of malignant effusions. There are no prospective, definitive studies comparing surgical management and pericardiocentesis. Frequently, surgical approaches are used because of concerns about reaccumulation. Large malignant effusions treated with simple pericardiocentesis without prolonged catheter drainage reaccumulate in as many as 60% of cases. However, several studies have indicated that when a pericardial drain is left in place for several days until drainage is < 25 mL/d (average 4.8 days), the risk of reaccumulation is low—approximately 12%. Sclerotherapy has a similar failure rate, and the 30-day mortality risk of a pericardial window is approximately 8%. Therefore, pericardiocentesis with drain placement is a very reasonable initial procedure for the diagnosis and management of malignant effusions.

III. CONTRAINDICATIONS

A. Absolute. In emergent scenarios of cardiac tamponade, when circulatory collapse is imminent, there are no absolute contraindications. In these instances, pericardiocentesis is often a lifesaving intervention.

B. Relative

1. **Anticoagulation.** The risk of bleeding is low with pericardiocentesis; however, if time permits, prothrombin time and partial thromboplastin time (PTT) should be obtained in all patients undergoing pericardiocentesis. An international normalized ratio > 1.8 or PTT greater than twice the normal should be allowed to normalize or be managed with fresh frozen plasma before intervention. It should also be noted that **tamponade physiology, by leading to hepatic congestion, may produce or exacerbate coagulation abnormalities**.
2. **Thrombocytopenia.** Platelet counts should be > 50,000.
3. **Traumatic hemopericardium.** A patient with traumatic hemopericardium should be treated surgically.
4. **Type A aortic dissection.** Typically, hemorrhagic effusions secondary to type A dissections are treated emergently with surgery. However, in situations where tamponade and circulatory collapse are imminent, small volume (10 to 25 mL) pericardiocentesis is indicated to stabilize patients before surgery. Data suggest that larger volume taps may be detrimental. In general, however, effusions in the setting of a type A dissection should be treated with emergent surgery.
5. **Subacute free wall rupture.** As with dissections, free wall ruptures are best addressed surgically, but small volume taps may be necessary to stabilize patients in preparation for operative repair.
6. **Small, loculated, or posteriorly located effusions** are technically more difficult to tap and have increased risk of complication. Echocardiographic guidance is paramount if pericardiocentesis is attempted.
7. **Purulent effusions.** While suspected purulent or tuberculous effusions are considered an indication for pericardiocentesis, grossly infected pericardial fluid should be managed surgically.
8. **Malignant effusion.** As stated previously, management of malignant effusions is controversial. Although pericardiocentesis is an effective and proven first-line therapy, recurrent effusions should be considered for pericardial window.

IV. PERICARDIOCENTESIS VERSUS SURGICAL MANAGEMENT (Table 69.1). The choice of procedure for pericardial drainage varies depending on the underlying etiology of the effusion, chronicity, size, hemodynamic impact, and suspected recurrence rate. Surgical techniques include complete pericardiectomy, partial pericardiectomy, subxiphoid pericardiotomy, anterior transthoracic window, and pleuropericardial window—collectively carrying an 80% to 90% success rate depending on the patient and indication. When comparing with pericardiocentesis for drainage of effusions, however, the first surgical option is typically pericardial window. Pericardiectomy is typically limited to permanent constriction.

There is a dearth of prospective data regarding the best approach to managing pericardial effusions. Most of the data are empirical and management is often clinician-, institution-, and patient-dependent. General recommendations for percutaneous versus surgical management of effusions are listed in Table 69.1.

V. PATIENT PREPARATION. Ideally, pericardiocentesis is performed in a laboratory equipped for fluoroscopy and invasive hemodynamic monitoring.

A. Informed consent. Patients should receive a clear explanation of the risks and benefits of pericardiocentesis, including the rationale for performing the procedure.

B. Monitoring. Patients should have heart rate, blood pressure, and oxygen saturations measured throughout the procedure. In addition, electrocardiographic monitoring is necessary. Worsening hemodynamics or falling oxygenation should alert the operator to the possibility of a procedural complication. Frequent ectopy (premature ventricular contractions, premature atrial contractions, or nonsustained ventricular tachycardia) may indicate impending perforation of a cardiac chamber. Some authorities recommend pulmonary artery catheter placement prior to performing a tap; however, for routine cases, this is not necessary.

C. Sedation. Pericardiocentesis is an anxiety-producing procedure for the patient. Appropriate pain relief and sedation should be administered prophylactically when this is clinically indicated and where it will not interfere with an already tenuous hemodynamic or respiratory state.

VI. TECHNIQUES

A. Echo guided. Currently, ultrasound-guided pericardiocentesis is the standard approach at most institutions. Patients are placed supine or in a slightly left lateral decubitus position. The head is elevated approximately 30°, and a complete echocardiographic evaluation is performed with standard parasternal, apical, and subcostal

TABLE 69.1 Approach to Pericardial Drainage

Pericardiocentesis	Surgical management
Most cases of cardiac tamponade	Cardiac tamponade due to aortic dissection or cardiac trauma; recurrent tamponade
Large or symptomatic effusions refractory to medical treatment	Recurrence of large chronic effusions after failed pericardiocentesis
High suspicion of tuberculous, purulent, or neoplastic pericarditis	Purulent effusion
	Loculated effusion
	Need for pericardial biopsy
	Coagulopathy

views. Attention is focused on the site where the greatest amount of pericardial fluid is closest to the skin surface. In addition, the liver should be identified to avoid accidental laceration during the procedure. Because it is air filled, lung tissue will block ultrasound waves and preclude imaging of the heart; consequently, the risk of pneumothorax is low if a good echocardiographic window is selected for the tap. While imaging, it is imperative to take note of the distance to the fluid pocket as well as ***the probe trajectory***. Failure to maintain an appropriate trajectory is a common cause of failure in accessing a pericardial effusion percutaneously. Obviously, the trajectory of the needle during the pericardiocentesis should be identical to the trajectory of the echocardiographic probe when imaging. The echo may be used in real time to help monitor the needle tip during insertion, especially with the assistance of a second operator, although real time is not always necessary in the case of large effusions.

1. **Prepping the patient.** Once the best window is selected, the probe's location is marked with a permanent marker and scrubbed with sterile chlorhexidine-alcohol or povidone-iodine solution. The entire torso is draped with sterile towels. The patient should not move between the echocardiographic examination and the procedure.
2. **Marking the needle.** Using a sterile pen, a mark can be made on the pericardiocentesis needle at the approximate distance between the skin and effusion that was noted on the echocardiogram. The needle used should be 5 to 8 cm in length, with a short bevel to lessen the risk of lacerating structures at the needle's tip. In some instances, particularly in obese patients, longer needles will be needed. It is imperative to know in these situations how far the needle should be inserted before pericardial fluid is expected.
3. **Anesthetic.** Local anesthetic (e.g., 1% lidocaine) is applied to the skin over the mark. Then deeper anesthetic is given over the superior aspect of the rib (if a chest wall approach is used).
4. **Entering the pericardium.** Using a three-way stopcock, an 18G Cook needle is attached to a syringe that contains a few more milliliters of local anesthetic. The needle is advanced through the anesthetized tract, over the rib, along the same trajectory as the echocardiographic probe, until fluid is aspirated. Alternatively, a sheathed catheter may be used instead of the Cook needle. Upon aspiration of fluid, the catheter is advanced over the needle, and the needle is withdrawn.
5. **Confirming catheter/needle placement.** While imaging from a remote location, agitated saline may be injected through the stopcock. **The appearance of bubbles in the pericardial space confirms an appropriate location**. Bubbles appearing within a cardiac chamber suggest that the heart has been perforated and that the needle or catheter should be withdrawn. If agitated saline cannot be visualized, one should consider an intrathoracic needle position. If effusions are large, the agitated saline may not be visible from all echocardiographic windows; occasionally, it may be necessary to reinject saline and image from an alternative location.
6. **Placing the pericardial catheter.** Once the intrapericardial position is confirmed, a floppy-tipped, 0.035" guidewire is inserted through the needle into the pericardial space. A blade scalpel is then used to nick the skin over the needle, the needle is withdrawn, and a 6F dilator is used to broaden the tract into the pericardium. Finally, the dilator is removed and a 6F to 8F pigtail angiocatheter with side holes is threaded over the wire well into the pericardial space. The wire is removed, and catheter placement can again be confirmed with agitated saline injection. With a three-way stopcock, the catheter is then attached to a 30-cm length of plastic tubing, which in turn may be connected to a vacuum bottle or drainage bag. The catheter should be sutured in place.
7. **Bloody pericardial fluid or frank blood?** Occasionally, very bloody fluid may be aspirated during pericardiocentesis, and confirmation of the needle placement may be difficult. Therefore, differentiating between blood (chamber perforation)

and bloody effusion can be challenging. A few milliliters of the aspirate can be placed on a gauze pad; classical teaching suggests that if the fluid coagulates, it is blood from chamber perforation. Conversely, fluid that spreads out on the gauze forming a pinkish halo suggests an intrapericardial origin. In reality, effusions caused by cardiac rupture, dissection, or ongoing bleeding into the pericardial space may clot upon aspiration; this fluid should be sent for hematocrit (to confirm that it is blood), and cardiothoracic surgery consultation should take place emergently.

B. Electrocardiographic guidance. Electrocardiographically guided pericardiocentesis may be used if echocardiography is unavailable or it may be used in conjunction with echocardiography. However, most authorities agree that electrocardiographic guidance adds little to the safety of a carefully performed echocardiographically guided procedure. If used instead of echocardiography, a subxiphoid approach is typically preferred:

(1) The patient is positioned at a 45° incline.

(2) Electrocardiographic limb leads are attached to the patient in the usual fashion.

(3) The xiphoid process is identified, and a point just inferior and to one side of the process is marked.

(4) The region is prepared and draped sterilely, and local anesthetic is given around the mark with a 25G needle.

(5) A 21G steel spinal needle is attached to a syringe filled with local anesthetic. The needle should be approximately 10 cm long. With a sterile alligator clip, the V lead of the electrocardiography monitor is attached to the metal hub of the spinal needle.

(6) The needle should be directed posteriorly at approximately 90° to the patient until the tip is below the costal margin. Then the hub of the needle should be depressed toward the patient's skin and advanced toward the left shoulder at an angle of 15° to 30° to the patient. Local anesthetic is injected as needed, and gentle suction should be applied to the syringe when advancing.

(7) ST elevations or premature ventricular contractions on the electrocardiography monitor indicate that the needle is encountering the right ventricle. PR-segment elevation or frequent premature atrial contractions (PAC) indicate that the needle is penetrating the right atrium. In the average adult, the distance from skin to pericardium is approximately 6 to 8 cm (1).

(8) Once in the pericardial space, a catheter may be placed as described previously.

C. Fluoroscopic guidance. Fluoroscopy can be used as well to guide pericardiocentesis, although this approach has largely been supplanted by echocardiography. With fluoroscopy, a subxiphoid approach is again used. The needle is directed to the left shoulder and toward the anterior diaphragmatic border of the right ventricle. Upon penetration into the pericardial space, needle position may be confirmed with injection of radiopaque contrast media. A drainage catheter may then be placed as described earlier.

D. Blind approach. In emergent conditions, blind pericardiocentesis may be necessary. A subxiphoid approach is used as described above. However, because of the significantly higher rates of complications, blind taps should be avoided unless absolutely necessary.

VII. DIAGNOSTIC STUDIES. If the cause of the pericardial effusion is not clear, fluid should be sent for analysis. The primary causes of idiopathic effusions depend somewhat on the patient population but include tuberculosis (TB), viral infection, uremia, collagen vascular disease, neoplasia, surgery, and myocardial infarction. Therefore, all fluid from idiopathic effusions should be sent for bacterial, mycobacterial, and viral cultures; cytologic examination; acid-fast bacillus smear; cell count; protein; glucose; and lactate dehydrogenase. If TB is suspected, evaluate for adenosine deaminase, interferon gamma, pericardial lysozyme, and polymerase chain reaction. If malignancy is suspected, tumor

markers can be sent for evaluation. Blood samples should be sent for chemistry, complete blood count, blood cultures (if bacterial infection is likely), thyroid-stimulating hormone, erythrocyte sedimentation rate/C-reactive protein, antinuclear antibody, and rheumatoid factor (if connective tissue disease is suspected). Consideration should also be given to conducting a tuberculin purified protein derivative skin test.

VIII. COMPLICATIONS.

Using echocardiographic guidance, the rate of complications is low. The largest series of echo-guided pericardiocenteses comes from the Mayo Clinic. Among the 1,127 procedures studied, major complications occurred in 1.2% of cases, and these included one death from right ventricular perforation, five nonfatal perforations that required surgery, one intercostal artery laceration, five pneumothoraces, one episode of sustained ventricular tachycardia, and one episode of bacteremia. Minor complications occurred 3.5% of the time and included 11 chamber perforations that sealed spontaneously, 8 self-limited pneumothoraces, 9 pleuropericardial fistulas, and 2 episodes of nonsustained ventricular tachycardia.

Fluoroscopy appears to be associated with higher rates of complications. In one series of 352 procedures, complications included 2 (0.6%) deaths, 23 (5.6%) chamber perforations (3 requiring surgery), 5 (1.4%) arterial bleeds (3 diaphragmatic, 1 posterior descending artery, and 1 left internal mammary artery), and 2 pneumothoraces (2).

Blind pericardiocentesis has been associated with morbidity rates as high as 20% and mortality rates as high as 6%.

Therefore, complications are relatively rare in experienced centers, although one must be mindful of the following:

A. Pneumothorax. This is usually effectively avoided with echocardiographic imaging. If the parasternal approach is used, remaining close to the sternum decreases the risk of pneumothorax.

B. Chamber entry/cardiac laceration. This is usually asymptomatic and self-sealing, particularly if the left ventricle is entered. Right ventricular perforations have a somewhat higher likelihood of bleeding when perforated, but right atrial lacerations carry the highest risk. If laceration is suspected, the needle or catheter should be withdrawn and the patient should be observed overnight in an intensive care setting. Serial echocardiograms are indicated to assess for changes in effusion size.

C. Arterial laceration. The left internal thoracic/mammary artery runs down the chest wall about 1 to 2 cm lateral to the sternum, with the vein running slightly more medial (3). Left chest wall and subxiphoid approaches must take this anatomy into consideration. The posterior descending artery can be lacerated on subxiphoid approaches if the needle is aimed too medially. On a chest wall approach, the intercostal arteries are avoided by passing the catheter just superior to the rib.

D. Infection. Sterile technique during the procedure and meticulous catheter care afterward if a drain is left in place minimize this risk. As the Mayo series suggests, the risk of catheter-related infection is very low, even among cancer patients.

E. Death. This is exceptionally rare when procedures are performed by experienced operators with echocardiographic guidance.

IX. POSTPROCEDURE CARE

A. Chest radiography. A postprocedure chest film should be obtained in all patients to exclude pneumothorax.

B. Monitoring. Patients should be observed for 1 to 2 hours following the pericardiocentesis. Patients without significant comorbidities who have uncomplicated diagnostic taps do not require inpatient care following the procedure.

C. Drain care. Care of an indwelling pericardial catheter is similar to that for any central line. After the catheter is sutured in place, the site is treated with an antibacterial ointment and then dressed sterilely. The dressing should be changed every 2 or 3 days.

1. The drain should be aspirated every 6 hours. Continuous drainage can also be used, but the risk of catheter obstruction is higher. Following aspiration, the catheter is flushed with sterile or heparinized saline.
2. If the fluid becomes purulent or the patient becomes septic, the catheter must be removed.
3. Strict record of the volume of fluid draining from the catheter must be kept. The catheter is typically left in place for 1 to 2 days, but extended drainage has been associated with lower rates of effusion recurrence. When the drainage is < 25 to 50 mL/d, the catheter can be removed.

D. Follow-up echocardiography. Before pulling the drain, an echocardiogram should be obtained to ensure resolution of the effusion.

E. Patient care. Patients may be ambulatory with the drain securely in place. Pericardial pain is best managed with nonsteroidal anti-inflammatory medications.

Commonly Used Cardiovascular Formulae

GENERAL HEMODYNAMICS

Mean arterial pressure (mm Hg) = Diastolic blood pressure (BP) + 1/3 (Systolic BP – Diastolic BP)

Stroke volume (mL) = End-diastolic volume – End-systolic volume

Cardiac output (L/min) = Heart rate × Stroke volume

Ohms law $V = IR$

V = Pressure difference across the system

I = Cardiac output or flow

R = Resistance across the system

$$\textbf{Systemic vascular resistance (Wood unit)} = \frac{\text{Mean arterial pressure} - \text{Central venous pressure}}{\text{Cardiac output}}$$

$$\textbf{Pulmonary vascular resistance (Wood unit)} = \frac{\text{Mean PA pressure} - \text{Mean PCWP}}{\text{Cardiac output}}$$

PA, pulmonary artery; PCWP, pulmonary capillary wedge pressure

1 Wood unit = 80 dynes/s/cm^5

$$\textbf{Pulmonary vascular resistance (echo)} \text{ (Wood unit)} = \left(\frac{\text{Tricuspid regurgitation velocity}}{\text{RVOT VTI}}\right) \times 10 + 0.16$$

RVOT, right ventricular outflow tract; VTI, Velocity Time Integral

Transpulmonary gradient (mm Hg) = Mean PAP – PCWP

PAP, pulmonary artery pressure; PCWP, pulmonary capillary wedge pressure

Fick equation

$$\text{Cardiac output (L/min)} = \frac{\text{Vo}_2 \text{ (mL/min)}}{1.36 \text{ (mL O}_2\text{/g Hgb)} \times \text{Hgb (g/dL)} \times 10 \text{ (dL/L)} \left[\text{Sa}_{\text{O}_2} - \text{Sv}_{\text{O}_2}\right]}$$

Vo_2 (oxygen consumption)

$$\textbf{Cardiac index (L/min/m}^2\text{)} = \frac{\text{Cardiac output (L/min)}}{\text{Body surface area (m}^2\text{)}}$$

Body surface area (m^2) = [Height (cm) + Weight (kg) – 60]/100

$$\text{Dubois formula for body surface area (m}^2\text{)} = \sqrt{\frac{\text{Height (cm)} \times \text{Weight (kg)}}{3{,}600}}$$

Stroke work (g-m/beat) = Stroke volume × Mean arterial pressure × 0.0144

Stroke work index (g-m/m^2/beat) = $\frac{\text{Stroke work}}{\text{Body surface area}}$

Coronary flow reserve = $\frac{\text{Peak coronary velocity at maximal hyperemia}}{\text{Peak coronary velocity at baseline}}$

Fractional flow reserve = $\frac{\text{Mean distal coronary pressure beyond stenosis}}{\text{Mean aortic pressure}}$

VALVULAR DISEASE AND LEFT VENTRICULAR (LV) FUNCTION

Gorlin equation

Aortic valve area (cm^2) = $\frac{\text{Cardiac output (mL/min)}}{44.3 \times \text{Systolic ejection period (s/beat)} \times \text{Heart rate (beats/min)} \times \sqrt{\text{Mean gradient}}}$

Mitral valve area (cm^2) = $\frac{\text{Cardiac output (mL/min)}}{38 \times \text{Diastolic filling period (s/beat)} \times \text{Heart rate (beats/min)} \times \sqrt{\text{Mean gradient}}}$

Hakki equation

Aortic valve area (cm^2) = $\frac{\text{Cardiac output}}{\sqrt{\text{Peak to peak gradient}}}$ or $\frac{\text{Cardiac output}}{\sqrt{\text{Mean gradient}}}$

Mitral valve area (cm^2) = $\frac{\text{Cardiac output}}{\sqrt{\text{Mean gradient}}}$

Simplified Bernoulli equation

Pressure difference = 4 v^2

If proximal velocity > 1 m/s, then pressure difference = 4 [(distal jet velocity)^2 – (proximal velocity)^2]

Continuity aortic valve area (cm^2) = $\text{Diameter}_{\text{LVOT}}^2 \times 0.785 \times \frac{\text{VTI}_{\text{LVOT}}}{\text{VTI}_{\text{Aortic valve}}}$

LVOT, left ventricular outflow tract; VTI, velocity time integral

Dimensionless index = $\frac{\text{VTI}_{\text{LVOT}}}{\text{VTI}_{\text{Aortic valve}}}$

VTI, velocity time integral; LVOT, left ventricular outflow tract

Stroke volume (mL) = $\text{Diameter}_{\text{LVOT}}^2 \times 0.785 \times \text{VTI}_{\text{LVOT}}$

VTI, velocity time integral; LVOT, left ventricular outflow tract

Aortic regurgitant fraction (%) = $\frac{\text{Aortic regurgitant volume}}{\text{LVOT stroke volume}} \times 100$

LVOT, left ventricular outflow tract

Mitral valve area (mitral stenosis) (cm^2) = $\frac{220}{\text{Pressure half time}}$

Tricuspid valve area (tricuspid stenosis) (cm^2) = $\frac{190}{\text{Pressure half time}}$

Pressure half time (ms) = 0.29 × Deceleration time

Proximal isovelocity surface area (PISA) method in mitral regurgitation

$$\text{Regurgitant orifice area (cm}^2\text{)} = \frac{6.28\, r^2 \times \text{Aliasing velocity}}{\text{Mitral regurgitation velocity}}$$

r, radius of PISA

Simplified PISA when aliasing velocity ~40 cm/s and peak continuous wave mitral regurgitation velocity ~5 m/s

$$\text{Regurgitant orifice area (cm}^2\text{)} = \frac{r^2}{2}$$

r, radius of PISA

Mitral regurgitant volume (mL) = $1.9r^2 \times$ Aliasing velocity

r, radius of PISA

$$\textbf{Mitral regurgitant fraction } (\%) = \frac{\text{Mitral regurgitant volume}}{\text{Mitral valve flow}} \times 100$$

$$\textbf{Fractional shortening } (\%) = \frac{\text{LVED dimension} - \text{LVES dimension}}{\text{LVED dimension}} \times 100$$

LVED, left ventricular end diastole; LVES, left ventricular end systole

$$\textbf{Ejection fraction } (\%) = \frac{\text{End diastolic volume} - \text{End systolic volume}}{\text{End diastolic volume}} \times 100$$

Estimated pulmonary artery systolic pressure (mm Hg) =
RA pressure + 4 × (Peak tricuspid regurgitation velocity)^2

RA, right atrium

Estimated pulmonary artery end-diastolic pressure (mm Hg) =
RA pressure + 4 × (Pulmonary regurgitation end-diastolic velocity)^2

RA, right atrium

Assessment of right atrial (RA) pressure (by echo)

IVC diameter (cm)	IVC collapse	Estimated RA pressure (mm Hg)
≤ 2.1	> 50%	3 (range 0–5)
≤ 2.1	< 50%	8 (range 5–10)
> 2.1	> 50%	8 (range 5–10)
> 2.1	< 50%	15 (range 10–20)

IVC, inferior vena cava

Left atrial (LA) pressure (mm Hg) =
Systolic blood pressure − 4 × (Mitral regurgitation velocity)^2

LV mass (area length) = $1.05\{[5/6\ A1(a + d + t)] - [5/6\ A2\ (a + d)]\}$

A1 = area of LV short axis using epicardial perimeter

A2 = area of LV short axis using endocardial perimeter

t = myocardial thickness

a = long axis length from widest minor axis radius to apex

b = short axis radius

d = truncated long axis from widest short axis diameter to mitral annulus plane

Dp/dt $= \dfrac{32{,}000 \text{ mm Hg}}{dt \text{ (in seconds)}}$

Dt, time it takes velocity to go from 1 to 3 m/s

Tei index (myocardial performance index) =

$$\frac{\text{Isovolumic contraction time} + \text{Isovolumic relaxation time}}{\text{Ejection time}}$$

SHUNTS

Shunt fraction $(Q_p/Q_s) = \dfrac{(Sao_2 - Svo_2)}{(Pvo_2 - Pao_2)}$

Sao_2, systemic arterial oxygen saturation

Svo_2, systemic venous oxygen saturation

Pvo_2, pulmonary venous oxygen saturation

Pao_2, pulmonary arterial oxygen saturation

Mvo_2 (%) $= \dfrac{3 \times (\text{SVCsat}) + (\text{IVCsat})}{4}$

Mvo_2, mixed venous saturation

SVC, superior vena cava

IVC, inferior vena cava

Q_p/Q_s (echo) $= \dfrac{\text{RVOT Cross-sectional area} \times \text{RVOT TVI}}{\text{LVOT Cross-sectional area} \times \text{LVOT VTI}}$

RVOT, right ventricular outflow tract

VTI, velocity time integral

LVOT, left ventricular outflow tract

ELECTROPHYSIOLOGY/ECG

QT_c (ms) $= \dfrac{QT}{\sqrt{\text{RR interval (seconds)}}}$

Heart rate (beats/min) $= \dfrac{60{,}000}{\text{Cycle length (ms)}}$

Left ventricular hypertrophy

Limb lead criteria

(1) R wave in lead I + S wave in lead III > 2.5 mV
(2) R wave in aVL > 1.1 mV
(3) R wave in aVF > 2.0 mV
(4) S wave in aVR > 1.4 mV

Precordial lead criteria

(1) R wave in V_5 or V_6 > 2.6 mV

(2) R wave in V_6 + S wave in V_1 > 3.5 mV

(3) Largest R wave + largest S wave in precordial leads > 4.5 mV

Cornell criteria

R wave in aVL + S wave in V_3 > 2.0 mV for females and 2.8 mV for males

Duke treadmill score (DTS)

DTS = Exercise time (minutes) − (5 × Maximal ST deviation) − (4 × Angina score)

0 = no angina

1 = nonlimiting angina

2 = angina limiting further testing

DTS ≤ −11 = high risk

DTS − 10 to 4 = moderate risk

DTS ≥ 5 = low risk

Age-predicted maximal heart rate (beats/min) = 220 − Age

PHARMACODYNAMICS

Volume of distribution (L) $= \dfrac{\text{Amount of drug in body}}{\text{Plasma drug concentration}}$

Loading dose (mg) $= \dfrac{\text{(Volume of distribution)} \times \text{(Plasma drug concentration)}}{\text{(Fraction of dose that is active)} \times \text{(Bioavailability of drug)}}$

Clearance (L/h) $= \dfrac{\text{Rate of drug administration}}{\text{Steady-state plasma drug concentration}}$

Half-life (h) $= \dfrac{0.693 \times \text{Volume of distribution}}{\text{Clearance (L/h)}}$

MISCELLANEOUS

Cockcroft-Gault

Glomerular filtration rate (mL/min) $= \dfrac{[(140 - \text{Age}) \times \text{Weight (kg)}]}{72 \times \text{Creatinine}}$

If female, multiply by 0.85

Ankle-Brachial index $= \dfrac{\text{Pedal pressure}}{\text{Brachial pressure (higher of two sides)}}$

Law of Laplace

Wall tension $= \dfrac{\text{Pressure} \times \text{Radius}}{\text{Wall thickness}}$

Central perfusion pressure = Mean arterial pressure − Intracranial pressure

Assessment of appropriateness of ascending aorta size to height

Aortic index = $\frac{\text{Maximal cross-sectional area of ascending aorta (cm}^2\text{)}}{\text{Height (m)}}$

If ratio > 10, consider repair of aorta

Cholesterol mg/dL to mmol/L

1 mg/dL = 0.02586 mmol/L; 1 mmol/L = 38.7 mg/dL

Thus, 130 mg/dL = 3.45 mmol/L

Total cholesterol = LDL cholesterol + HDL cholesterol + 0.20 (Triglyceride level)

HDL, high-density lipoprotein; LDL, low-density lipoprotein

STATISTICS

	Disease present	Disease absent
Test result positive	a (True positive)	b (False positive)
Tests result negative	c (False negative)	d (True negative)

Sensitivity = $\frac{a}{a+c}$

Specificity = $\frac{d}{b+d}$

Positive predictive value = $\frac{a}{a+b}$

Negative predictive value = $\frac{d}{c+d}$

Likelihood ratio for a positive test = $\frac{\text{Sensitivity}}{1-\text{Specificity}} = \frac{a/a+c}{b/b+d}$

Likelihood ratio for a negative test = $\frac{1-\text{Sensitivity}}{\text{Specificity}} = \frac{c/a+c}{d/b+d}$

	Outcome positive	Outcome negative
Treated group	a	b
Control group	c	d

Relative risk = $\frac{\text{Risk of outcome in treated group}}{\text{Risk of outcome in control group}} = \frac{a/a+b}{c/c+d}$

Relative risk reduction = (1 − Relative risk) × 100%

Absolute risk reduction = Difference in risk of outcome between control group and treated group

Absolute risk reduction = c/c + d − a/a + b

Number needed to treat = $\frac{1}{\text{Absolute risk reduction}}$

Odds ratio = $\frac{\text{Number of outcome events/Number of subjects}}{1-(\text{Number of outcome events/Number of subjects})}$

Alpha-glucosidase inhibitors, for diabetes, 745
Alteplase (tPA), in myocardial infarction treatment, 17, 22
Ambulatory blood pressure monitoring, 715
Amiodarone
  for atrial fibrillation, 435, 437t
  AV node, 370
  for sudden cardiac death prevention, 94–95, 383
  for ventricular tachycardia, 384
Amplatz catheters, in left heart catheterization, *1022*, *1023*, 1024
Amylin, for diabetes, 746
Amyloidosis, cardiac, 153
  primary, 153
  familial, 153
  senile, 153
Anaphylactic shock, 986
Anemia, high-output heart failure due to, 132
Anesthetic agents, perioperative hemodynamic monitoring and, 588
Aneurysm
  abdominal or thoracic, 1005
  aortic, 459–479, 643, 838, 854 (*See also* Aortic aneurysm)
  atrial septal, 517–518

Aneurysm (*continued*)
lower extremity, 488
in peripheral arterial disease, 480
ventricular, 68, 69
Angina (*See also* Chest pain)
in aortic stenosis, 241
decubitus, 98
nocturnal, 98
recurrent, as myocardial infarction complication, 56
stable (*See* Stable angina)
unstable (*See* Unstable angina)
Angioedema, ACE inhibitor side effect, 143
Angiography
carotid, 497–498, *497*, *498*, 1035
catheter-based, 485
computed tomography
in carotid artery disease, 496
clinical applications for, 852–853
in peripheral arterial disease, 484–485, 490
in renal artery stenosis, 490
in thoracic aortic aneurysm, 477
coronary
in cardiac tumors, 674
following myocardial infarction, 88
limitations of, 1032
in myocarditis, 178
in percutaneous coronary intervention, 1043, 1043t
in peripheral arterial disease, 485, 485
in stable angina assessment, 101–102, 102t
left heart (*See* Left heart catheterization)
magnetic resonance, 836
in aortic dissection, 465
in carotid artery disease, 496
in peripheral arterial disease, 484
in pulmonary embolism, 453
in renal artery stenosis, 489–490
in thoracic aortic aneurysm, 477
pulmonary, in pulmonary embolism, 453
right heart (*See* Right heart catheterization)
AngioGuard, 504–505, *506*
Angioplasty
percutaneous balloon, in coarctation of the aorta, 534
percutaneous transluminal coronary, 1047–1048
Angiosarcomas, 676
Angioscopy, in percutaneous coronary intervention, 1047
Angioseal device, 1037
Angiotensin-converting enzyme (ACE) inhibitors
in acute coronary syndromes, 45, 56
in atrial fibrillation, 427
following myocardial infarction, 93
gender differences in application, 760
in heart failure, 141, 143, 143t, 157
in myocardial infarction treatment, 28
side effects, 141
in stable angina, 111
Angiotensin II receptor blockers (ARB), for heart failure, 143–144, 142t, 157
Ankle–brachial index, in peripheral arterial disease, 482, 483t
Anode, 907
Anorexigens, 225
Antiarrhythmic agents
in atrial fibrillation, 427
in hypertrophic cardiomyopathy, 166–167, 168t
in myocardial infarction treatment, 29
in sudden cardiac death, 416–417, 419, 421
Antibiotic therapy
in infective endocarditis, 336, 334t–335t, 337t, 339
in rheumatic fever, 353–354, 353t, 354t
Antibody-mediated rejection (AMR), 219
Anticardiac antibody titers, in myocarditis diagnosis, 177–178
Anticoagulant therapy
cardioversion and, 969–970, 971t
in carotid artery disease, 501
direct thrombin inhibitors, 52
factor Xa inhibitors, 52–53
following valve replacement, 314–315
GP IIb/IIIa inhibitors, 53–55
heparin, 51
initial conservative strategy, 48
initial invasive strategy, 48
low-molecular-weight heparin (LMWH), 51–52
medical therapy, 49
in mitral stenosis, 290
pregnancy and, 315
use during pregnancy, 631, 634–636, 633t–634t
in ventricular aneurysm, 69
Antihyperlipidemic therapy, 700–711
in acute coronary syndromes, 104–105
in aortic stenosis, 248
bile acid sequestrants, 706–707
in carotid artery disease, 500
cholesterol absorption inhibitors, 707–708
classification of, 700–701, 701t
fibrates, 707
high total cholesterol, 710
low HDLs, 90
nicotine acid or niacin, 707
in peripheral arterial disease, 486
post-myocardial infarction, 90–91
risk stratification, 702
in stable angina, 107
very high LDLs, 709
Antihypertensive therapy, 717–721
in carotid artery disease, 500–501
concomitant diseases, 719–720, 719t
dosage, 720
drug interactions, 720
emerging evidence, 720–721
older adults, 720
priorities of, 718
in renal artery stenosis, 490
Anti-ischemic therapy, 44–45
angiotensin-converting enzyme (ACE) inhibitors, 45
β-blockers, 44–45
calcium channel blockers, 45
nitrates, 44
Antimyosin scintigraphy, 178
Antioxidants, 94, 112, 761
Antiphospholipid antibodies, 457, 639
Antiphospholipid antibody syndrome, 639
Antiplatelet therapy
abciximab, 53

aspirin, 49
in carotid artery disease, 499–500
clopidogrel, 49–50
direct thrombin inhibitors (DTIs), 52
following myocardial infarction, 91
following percutaneous coronary intervention, 1051, 1057
initial invasive strategy, 48
low-molecular-weight heparin (LMWH), 51–52
in peripheral arterial disease, 485–486
prasugrel, 50–51
ticlopidine, 49
thienopyridines, 91–92
warfarin, 92
Antithrombin defects, 455–456
Antithromboembolic agents, in atrial fibrillation, 427–431, 428t, 430t
Aorta
anatomic considerations, 459–460

in myocardial infarction diagnosis, 5
in pulmonary embolism, 451
Cardiac tumors, 672–678
benign, 674–676, 675t
cardiovascular computed tomography in, 853–854
clinical presentation, 672–673
diagnosis, 673–674
differential diagnosis, 677
embolization in, 672–673
magnetic resonance imaging in, 843
malignant, 675t, 676–677
metastasis, 677, 677t
physical examination, 673
primary, 674–676
secondary, 677
therapy, 677–678
Cardioactive drugs, for electrophysiologic testing, 866–867
Cardiogenic shock
complicating acute MI, 77–84, 80t
classification, 79t
clinical presentation, 78
diagnostic studies, 80–81
etiology, 79–80
laboratory testing, 80
pathophysiology, 80, *81*
refractory shock, management of, 83–84
risk stratification, 78–79
therapy, 81–82
etiology, 63, 69
left ventricular pump failure and, 69
myocardial infarction and, 1003
Cardiomegaly, in pericardial effusion, 664

Cardiomyopathy
arrhythmogenic right ventricular, 135, 383–384, 685–686, *954*
Chagas' disease, 180
diabetic, 130
dilated, 130
familial, 130
gene expression profiling in, 683–684, 684t
idiopathic, 388
magnetic resonance imaging in, 840–841
in ventricular tachycardia, 381–383
gene expression profiling in, 683–684
in heart failure, 130–131
hypertensive, 130
hypertrophic, 160–175
with arrhythmia, 166–167, *167*, 168t
vs. Athlete's heart, 172–173
with atrial fibrillation, 166, *167*
atrial fibrillation and, 443
cardiac pacing in, 906
clinical presentation, 160–161
defined, 160
diagnostic testing, 163–165
differential diagnosis, 160, 161t
gene expression profiling in, 684–685
genetic aspects of, 163, 163t
infective endocarditis and, 173, 157t
in heart failure, diagnosis of, 152
magnetic resonance imaging in, 841
management strategies, 165–172, *167*
mitral regurgitation and, 164–165
with obstruction, 164
in older adults, 174
physical examination, 162, 162t
pregnancy and, 626–627
stress echocardiography in, 822–823
in sudden cardiac death, 412
sudden cardiac death in, 161, 163, 172
syncope in, 161
in ventricular tachycardia, 383
Yamaguchi's, 173–174
idiopathic dilated, in sudden cardiac death, 412
inflammatory (*See* Myocarditis)
ischemic, 130
surgical revascularization for, 187–188
left ventricular noncompaction, 686–687
magnetic resonance imaging in, 840–841
peripartum, 131, 177, 630–631
restrictive
defined, 150
idiopathic, 153
magnetic resonance imaging in, 841
right heart cardiac catheterization in, 985t, 987, 989t
in rheumatoid arthritis (RA), 637
tachyarrhythmia-induced, 131
toxin-mediated, 131
Cardiomyoplasty, dynamic, 190
Cardiopulmonary exercise testing, in right heart catheterization, 137
Cardiopulmonary resuscitation (CPR), in sudden cardiac death, 415
Cardiopulmonary testing
in tetralogy of Fallot, 541
in transposition of the great arteries, 475
Cardiotoxic agents, in heart failure, 130–131
Cardiovascular computed tomography, 845–855
angiography
in carotid artery disease, 496
clinical applications for, 851–855
in peripheral arterial disease, 484–485
in pulmonary embolism, 452
in renal artery stenosis, 490
in thoracic aortic aneurysm, 477
in aortic aneurysm, 854
in aortic dissection, 465, 854
in bypass graft imaging, 853
in cardiac tumors, 674
clinical applications, 851–855
in congenital heart disease, 854
contraindications, 849–850
contrast, 848
three dimensional or volume rendering, 848
four-dimensional or cine imaging, 848
electron beam, 847
image acquisition, 847–848
indications, 848–849, 849t
maximal-intensity projections, 848
multidetector, 846–847
multiplanar reformation, 848
in pericardial effusion, 667, 855
physics of, 846
safety considerations, 850, 851t
technical challenges in, 846
triple scan, in chest pain emergency department evaluation, 610
in ventricular dysplasia, 853
in ventricular septal defect, 524
Cardiovascular disease
chromosomal abnormalities and, 689, 691, 691t
gender differences
assessment, 757–758
cardiac risk factors, 755–757
clinical presentation, 757
further considerations, 765
prevention, 761–764, 763t–764t
risk stratification, 761–764, 762t
therapy, 758–761
morbidity and mortality, 694
systemic diseases (*See* Systemic diseases)
Cardiovascular risk factors
c-reactive protein, 725
CHADS risk index, 428
Detsky Modified Cardiac Risk Index, 576, 578t
fibrinogen, 728
gender differences, 755–757
genetic factors, 729
Goldman Multifocal Cardiac Risk Index, 576, 577t–578t
homocysteine, 727–728
hyperlipidemia, 694–711
hypertension, 713–721
lipoprotein(a) or Lp(a), 726–727
myeloperoxidase, 729
obesity, 721–722
Revised Cardiac Risk Index, 579, 579t
sedentary lifestyle, 724–725
tobacco, 722–724

Cardioversion
electrical, 968–975
anticoagulant therapy and, 970, 970t
in atrial fibrillation, 431–432, 970t, 973t
in atrial flutter, 363, 973t
complications, 973–974
contraindications, 968, 969t, 970t
defined, 968
electrode placement, 971–972, *972*
energy selection, 972–973, 973t
implantable cardioverter-defibrillators and, 975
indications, 968, 969t, 970t
mechanisms, 968
pacemakers and, 903, 975
patient preparation, 968–970
pregnancy and, 975
sedation, 972
synchronization, 973
troubleshooting, 974–975
pharmacologic, in atrial fibrillation, 432–433, 432t
CardioWest implant, 193–194
Carditis
radiation, 153–154
in rheumatic fever, 348–349, 352
CARE-HF trial, 418, 924–925
Carotid angiography, 497–498, *498*, 1035
Carotid artery
anatomic considerations, 492–493, *493*, *494*
bruits, 495
Carotid artery disease, 492–507
anatomic considerations, 492–493, *493*, *494*
complications of, 502, 505–507
diagnostic tests, 495–498
management, 498–507
carotid endarterectomy, 501–503, 507
carotid stenting, 507, 507
medical, 498–501
risk factor modifications, 498–499
pathophysiology, 495
risk factors for, 493, 495
Carotid endarterectomy, 501–503, 507
Carotid sinus hypersensitivity, 398t, 410–411, 889t
Carotid sinus massage, 393–394, 410, 868–869
Carotid stenting, 503–505, 507
Catecholaminergic polymorphic VT, 379, 413
Catheter ablation
with pulmonary vein isolation, in atrial fibrillation, 438–439
in ventricular tachycardia, 377
Catheterization (*See* Cardiac catheterization)
left heart (*See* Left heart catheterization)
right heart (*See* Right heart catheterization)
Catheters
electrode, for electrophysiologic testing, 859–860
for left heart catheterization, *1022*, *1023*, 1024
thrombus aspiration, in myocardial infarction treatment, 21
Cathode, 907
Cell-mediated rejection, 218
Centrifugal pump, circulatory support device, 193
Cerebrovascular accident (CVA)
fibrinolytic therapy, 22
hypertensive crisis and, 555
CHADS risk index, 428
Chagas' disease
heart failure, cause of, 132
ventricular tachycardia in, 384
Chemotherapeutic agents, in heart failure, 130–131
Chest pain (*See also* Angina)
cardiac *vs.* noncardiac, 606, 607t
emergency department evaluation of, 605–612
clinical presentation, 606–607
diagnostic tests, 607–610
differential diagnosis, 610–612, 611t
incidence, 605, *606*, 606t
risk stratification, 605, *606*
Chest radiography
in aortic dissection, 465
in atrial septal defect, 513
in cardiac tumors, 673
in cardiogenic shock, 80
in coarctation of the aorta, 533
in constrictive pericarditis, 656
in Ebstein anomaly, 553
in heart failure diagnosis, 135
for HFpEF, 152
in Ischemic MR (IMR), 279
in mitral stenosis, 289
in patent ductus arteriosus, 530
in pulmonary embolism, 451
in pulmonary hypertension, 227
temporary transvenous pacing and, 966
in tetralogy of Fallot, 540
in thoracic aortic aneurysm, 476
in transposition of the great arteries, 546
congenitally corrected, 550
in ventricular septal defect, 523
Cholecystitis, in myocardial infarction differential diagnosis, 5
Cholesterol
high (*See* Hyperlipidemia)
total
in classification of hyperlipidemia, 700–701, 701t
management of elevated, 709–710
Cholesterol absorption inhibitors, for hyperlipidemia, 707–708
Cholesteryl ester transfer protein (CETP) inhibitors, 708–709, 708t
Chromosomal abnormalities, cardiovascular disease and, 689, 691, 691t
Chronaxie, 885
Chronic heart failure (CHF), treatment, 187–198
circulatory support devices, 190–198
dynamic cardiomyoplasty, 190
endoventricular circular patch plasty (EVCPP), 189
mitral valve surgery, 188–189
partial LV resection, 189–190
surgical revascularization, 187–188
Chronotropic incompetence, defined, 391
Chronotropic response index, 788
Churg-Strauss syndrome (CSS), 642
Cilostazol, in claudication, 487
Cine imaging, 836, 848
Cinefluoroscopy, in prosthetic valve assessment, 320–321

Circulatory support devices
as bridge to transplantation, 197, 197t
in chronic heart failure (CHF), 190–198
background, 190
patient selection, 190–191
complications, 196–197

Pericardium
anatomic considerations, 646–647
trauma to, 614
Peripheral arterial disease (PAD), 480–491
lower extremity, 480–488
clinical presentation, 481–482, 481t, 482t
diagnostic tests, 482–485, 481t, *483*
etiology, 480–481
treatment, 485–488
lower extremity aneurysms, 488
overview, 480
renal artery stenosis, 488–491
treatment, 485–488
antiplatelet therapy, 485–486
revascularization, 486–488
risk factor modification, 486
upper extremity, 488
Peripheral pulse, in aortic regurgitation, 254
PFO CLOSURE, 1069–1071
complications, 1071
procedure, 1070–1071
outcomes, 1071
Pharmacologic cardioversion, in atrial fibrillation, 432–433, 432t
Phase-contrast velocity mapping, 836
Phentermine, 736
Phentolamine, 603
Phenylephrine, in hypertrophic cardiomyopathy, 168
PISA method, 258, 1088t, 1098–1099, 1103
Plaque, rupture of, in acute coronary syndromes, 40–41
Platelet glycoprotein IIb/IIIa antagonists (GP IIb/IIIa inhibitors) (*See* Glycoprotein IIb/IIIa inhibitors)
Platelet inhibitors, for stable angina, 104
Platelet P2Y12 receptor antagonists, in MI treatment, 16–17
Pneumocystis jiroveci pneumonia, following cardiac transplantation, 200
Pneumothorax, pacemaker complication, 898
Polarity, in cardiac pacing, 884
Polyarteritis nodosa (PAN), 642
Polyclonal anti-lymphocyte antibodies, in cardiac transplantation, 210t–211t, 215
Polymyositis (PM), 640
Portal hypertension, 225
Positive predictive value, 774
Positron emission tomography (PET), 806–807 (*See also* Nuclear imaging)
blood flow tracers, 806
clinical applications, 807
FDG, 806–807, 828
in hypertrophic cardiomyopathy, 161
metabolic agents, 806–807, 828
metabolic imaging, 807
in myocardial viability assessment, 807, 827–829
perfusion analyses, 804–805, 826–827
protocols, 807
quantitative analyses, 803–804
stress testing, 100
Possis AngioJet, in percutaneous coronary intervention, 1053
Postpartum period, normal changes during, 619
Postpericardiotomy syndrome (PPS), 648, 652
Postural orthostatic tachycardia syndrome (POTS, 573–574
etiology, 573
diagnosis, 574
treatment, 574
Prasugrel, 1057–1058
in acute coronary syndromes, 50–51
gender differences in application, 759–760
Prednisone, in acute pericarditis, 652
Preeclampsia, 628
Preexcitation syndromes, 366–368
LGL syndrome, 367–368
Mahaim fiber tachycardias, 367
Wolf-Parkinson-White syndrome
diagnostic tests, 369
pathophysiology, 367, *368*
risk stratification, 369
therapy, 370
Pregnancy
anticoagulation therapy and, 631–636
aortic dissection and, 462, 629–630
arrhythmias and, 630
atrial fibrillation during, 443
cardiac transplantation and, 631
cardiovascular disease and, 618–636
cardiovascular drugs and, 631, 632t, 633t–634t, 634–636
cardiovascular evaluation, 619–621, 620t
cardiovascular risk assessment, 621–623, 621t–622t
cardioversion and, 975
congenital heart disease and, 623–624
coronary artery disease and, 630
Eisenmenger syndrome and, 556, 624
hypertensive disorders, 627–631
Marfan's syndrome and, 629
normal changes during, 618–619, 619t, 620t
labor and delivery, 619
postpartum, 619
peripartum cardiomyopathy, 630–631
primary pulmonary hypertension and, 631
valve disease and, 624–627, 625t

Prehypertension, 714
Preoperative cardiac evaluation, echocardiography, 581
Preoperative coronary revascularization, 584–585
Preoperative medical therapy, 587–588
Pressure gradients
  intracardiac, 667–668
  transvalvular, 252, 245, 1095
Pressure half-time, 287, 320
Procainamide
  in atrial fibrillation, 433
  in electrophysiologic testing, 867
Propafenone, in atrial fibrillation, 432t, 434t, 435
Prophylaxis, for infective endocarditis, 173, 173, 343–345, 344t, 345t
Prostacyclin, 232–233
Prosthetic valves, 308–325
  acoustic characteristics of, 316, *316*

    clinical presentation, 315–316
    Dimensionless index, 320
    Doppler echocardiography, 317–321, 319t
    pressure half-time (PHT), 320
    transvalvular gradients, 319
    two dimensional echocardiography, 316–317
    valve area calculations, 319–320
  bioprosthetic
    anticoagulation therapy following placement, 314–315
    in aortic valve replacement, 251
    failure of, 325
    vs. mechanical, 311–314, 311t
    in tricuspid valve replacement, 299
    types of, 308–311, *309*
  complications related to, 321–325
    atrial fibrillation, 321
    dehiscence, 324
    embolic stroke, 325
    endocarditis, 321–322
    hemolysis, 322–323
    mechanical failure, 325
    pannus formation, 325
    patient-prosthesis mismatch, 324–325
    thrombosis, 323–324
  infective endocarditis and, 329–330
  mechanical
    anticoagulation therapy following placement, 314–315
    in aortic stenosis, 251
    vs. bioprosthetic, 314t, 315
    failure of, 325
    indications, 313
    types of, 314–315, 314t
  noncardiac surgical procedures and, 315, 585
  pregnancy and, 627, 629t
  repair *vs.* replacement, 312, 312t
  selection of valves, 311–314, 311t
  surgical follow-up, 314
Protein C defects, 455–456
Protein S defects, 455–456
Prothrombin gene mutation, 455
Proximal isovelocity surface area (PISA), 271–272, 271t, 258
Pseudoaneurysm, ventricular
  as myocardial infarction complication, 67–68
  in percutaneous coronary intervention, 1060
Pseudofusion, in cardiac pacing, 908
Pseudo-pseudofusion, 908
Pseudostenosis, aortic, 252
Pulmonary angiography, in pulmonary embolism, 453
Pulmonary arterial hypertension (PAH), 224
  non-PAH groups, 233
Pulmonary artery catheterization (*See also* Right heart catheterization)
  in percutaneous coronary intervention, 1047
  diastolic pressure, 1096
  in right heart cardiac catheterization
    catheter insertion, 981–983
    pitfalls of, 984
  systolic pressure, 1095–1096
Pulmonary capillary wedge pressure (PCWP)
  in cardiogenic shock, 78
  decreased, hypotension with, 29
  in right heart catheterization, 136
  increased, 29
  in mitral stenosis, *288*, 288
Pulmonary disease, atrial fibrillation and, 444
Pulmonary edema
  acute cardiogenic, in heart failure, 133

Preface

With *Pocket Cardiology,* we now offer those taking care of patients with complex cardiovascular disease a focused and concise reference to aid them in their daily clinical care. *Pocket Cardiology* has been designed to either supplant the Cardiology section in *Pocket Medicine* or serve as a stand-alone handbook. *Pocket Cardiology* provides greatly expanded coverage of the latest treatment options for the major common cardiovascular diseases as well as new sections on advanced heart failure, vascular, and electrophysiology topics.

We have incorporated key references to the most recent high-tier reviews and important studies published right up to the time *Pocket Cardiology* went to press. We welcome any suggestions for further improvement. Although the recommendations herein are as evidence based as possible, sound clinical judgement must be applied to every scenario.

This book would not have been possible without the help of Melinda Cuerda, who shepherded the project from start to finish, with an incredible eye to detail to ensure that each page of this book was the very best it could be.

It is a privilege to take care of patients, especially when working with the house officers, fellows, and attendings at Brigham and Women's Hospital and the Massachusetts General Hospital. The rapid advances in cardiovascular medicine are truly amazing. We hope the information contained within *Pocket Cardiology* proves useful in your quest to deliver the best possible care to your patients.

Marc S. Sabatine, MD, MPH

Coronary Disease

ELECTROCARDIOGRAPHY

Approach *(a systematic approach is vital)*

- **Rate** (? tachy or brady)
- **Rhythm** (? P waves, ? relationship between P and QRS, ? regular)
- **Intervals** (PR, QRS, QT) and **axis** (? LAD or RAD)
- **Chamber abnormality** (? LAA and/or RAA, ? LVH and/or RVH)
- **QRST changes** (? Q waves, poor R-wave progression V_1-V_6, ST ↑/↓ or T-wave Δs)

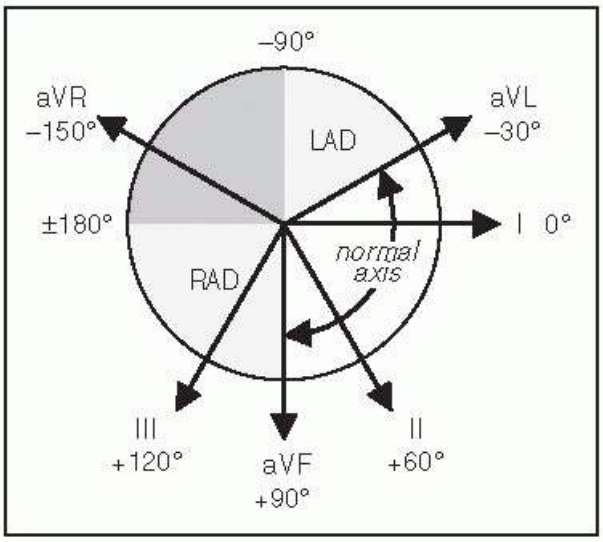

Figure 1-1 QRS axis

Left axis deviation (LAD)

- **Definition:** axis beyond -30° (S > R in lead II)
- **Etiologies:** LVH, LBBB, inferior MI, WPW
- **Left anterior fascicular block (LAFB):** LAD (-45 to -90°) *and* qR in aVL *and* QRS <120 msec *and* no other cause of LAD (eg, IMI)

Right axis deviation (RAD)

- **Definition:** axis beyond +90° (S > R in lead I)
- **Etiologies:** RVH, PE, COPD (usually not > + 110°), septal defects, lateral MI, WPW
- **Left posterior fascicular block (LPFB):** RAD (90-180°) *and* rS in I & aVL *and* qR in III & aVF *and* QRS <120 msec *and* no other cause of RAD

Bundle Branch Blocks (*Circ* 2009;119:e235)

Initial depol. is left-to-right across septum (r in V_1 & q in V_6; nb, absent in

Normal		LBBB) followed by LV & RV free wall, with LV dominating (nb, RV depol. later and visible in RBBB).
RBBB		1. QRS ≥120 msec (110-119 = incomplete) 2. rSR' in R precordial leads (V_1, V_2) 3. Wide S wave in I and V_6 4. ± ST↓ or TWI in R precordial leads
LBBB		1. QRS ≥120 msec (110-119 = incomplete) 2. Broad, slurred, monophasic R in I, aVL, V_5-V_6 (± RS in V_5-V_6 if cardiomegaly) 3. Absence of Q in I, V_5 and V_6 (may have narrow q in aVL) 4. Displacement of ST & Tw opposite major QRS deflection 5. ± PRWP, LAD, Qw's in inferior leads

Bifascicular block: RBBB + LAFB/LPFB. Trifascicular block: bifascicular block + 1° AVB (nb, misnomer as 1° AVB involves AV node but no fascicle per se).

Prolonged QT interval (*NEJM* 2008;358:169; www.torsades.org)

- QT measured from beginning of QRS complex to end of T wave (measure longest QT)
- QT varies w/ HR → corrected w/ Bazett formula: QTc = QT/$\sqrt{RR}$ (RR in sec, can be estimated by 60/HR), overcorrects at high HR and undercorrects at low HR (nl QTc <440 msec ♂ and <460 msec ♀)
- Fridericia's formula preferred at very high or low HR: QTc = QT/ $\sqrt[3]{RR}$
- QT prolongation a/w ↑ risk TdP (espec >500 msec); perform baseline/serial ECGs if using QT prolonging meds, no estab guidelines for stopping Rx if QT prolongs
- Etiologies:

  Antiarrhythmics: class Ia (procainamide, disopyramide), class III (amio, sotalol, dofet)

  Psych drugs: antipsychotics (phenothiazines, haloperidol, atypicals), Li, ? SSRI, TCA

  Antimicrobials: macrolides, quinolones, azoles, pentamidine, atovaquone, atazanavir

  Other: antiemetics (droperidol, 5-HT3 antagonists), alfuzosin, methadone, ranolazine

  Electrolyte disturbances: hypoCa (nb, hyperCa a/w ↑ QT), ± hypoK, ? hypoMg

  Autonomic dysfxn: ICH (deep TWI), stroke, carotid endarterectomy, neck dissection

  Congenital (long QT syndrome): K, Na, & Ca channelopathies (*Circ* 2013;127:126)

  Misc: CAD, CMP, bradycardia, high-grade AVB, hypothyroidism, hypothermia, BBB

ECG P-wave Criteria	**Left Atrial Abnormality (LAA)** 	**Right Atrial Abnormality (RAA)** 
Left ventricular hypertrophy (LVH) (*Circ* 2009;119:e251)

- Etiologies: HTN, AS/AI, HCMP, coarctation of aorta
- Criteria (all w/ Se <50%, Sp >85%; accuracy affected by age, sex, race, BMI)

  Romhilt-Estes point-score system (4 points = probable; 5 points = diagnostic):

Criteria	Points
Voltage (any of the following): R or S in limb leads ≥20 mm; S in V_1 or V_2 ≥30 mm; R in V_5 or V_6 ≥30 mm	3
ST-T displacement opposite to QRS deflection (either):	
◦ Pt not on digoxin	3
◦ Pt on digoxin	1
Left atrial enlargement	3
Left axis deviation	2
QRS duration ≥90 msec	1
Delayed intrinsicoid deflection (QRS onset to R peak) in V_5 or V_6 >50 msec	1

  Sokolow-Lyon: S in V_1 + R in V_5 or V_6 ≥35 mm or R in aVL ≥11 mm

  Cornell: R in aVL + S in V_3 >28 mm in men or >20 mm in women If LAD/LAFB, S in III + max (R+S) in precordium ≥30 mm

Right ventricular hypertrophy (RVH) (*Circ* 2009;119:e251)

- Etiologies: cor pulmonale, congenital (tetralogy, TGA, PS, ASD, VSD), MS, TR
- Criteria (all tend to be insensitive, but highly specific, except in COPD) R > S in V_1 or R in V_1 ≥7 mm, S in V_5 or V_6 ≥7 mm, drop in R/S ratio across precordium RAD ≥+110° (LVH + RAD *or* prominent S in V_5 or V_6 → *biventricular* hypertrophy)

Ddx of dominant R wave in V_1 or V_2

- Ventricular enlargement: RVH (RAD, RAA, deep S waves in I, V_5, V_6); HCMP
- Myocardial injury: posterior MI (anterior Rw = posterior Qw; often with IMI)
- Abnormal depolarization: RBBB (QRS > 120 msec, rSR'); WPW (↓ PR, δ wave, ↑ QRS)

- Other: dextroversion; Duchenne muscular dystrophy; lead misplacement; nl variant

Poor R wave progression (PRWP) (*Am Heart J* 2004;148:80)

- Definition: loss of anterior forces w/o frank Q waves (V_1-V_3); R wave in V_3 ≤3 mm
- Possible etiologies (nonspecific):

  old anteroseptal MI (usually w/ R wave V_3 ≤1.5 mm, ± persistent ST ↑ or TWI V_2 & V_3) cardiomyopathy

  LVH (delayed RWP with prominent left precordial voltage), RVH, COPD (which may also have RAA, RAD, limb lead QRS amplitude ≤5, $S_I S_{II} S_{III}$ w/ R/S ratio <1 in those leads)

  LBBB; WPW; clockwise rotation of the heart; lead misplacement; PTX

Pathologic Q waves

- Definition: ≥30 msec (≥20 msec V_2-V_3) or >25% height of R wave in that QRS complex
- Small (septal) q waves in I, aVL, V_5 & V_6 are nl, as can be isolated Qw in III, aVR, V_1
- "Pseudoinfarct" pattern may be seen in LBBB, infiltrative dis., HCM, COPD, PTX, WPW
- In WPW, Qw pattern may help localize site of accessory pathway (Bundle of Kent)

ST elevation (STE) (*NEJM* 2003;349:2128; *Circ* 2009;119:e241 & e262)

- **Acute MI** (upward convexity ± TWI) or prior MI with persistent STE
- **Coronary spasm** (Prinzmetal's angina; transient STE in a coronary distribution)
- **Pericarditis** (diffuse, upward concavity STE; a/w PR ↓ ; Tw usually upright)
- **HCM, Takotsubo CMP, ventricular aneurysm,** cardiac contusion
- **Pulmonary embolism** (occ. STE V_1-V_3; classically a/w TWI V_1-V_4, RAD, RBBB, $S_1Q_3T_3$)
- **Repolarization abnormalities**

  LBBB (↑ QRS duration, STE discordant from QRS complex) dx *of* MI *in setting of* LBBB*:* Sgarbossa criteria (*NEJM* 1996;334:481) ≥1 mm STE concordant w/ QRS (Se 73%, Sp 92%) STD ≥1 mm V_1-V_3 (Se 25%, Sp 96%) STE ≥5 mm discordant w/ QRS (Se 31%, Sp 92%)

  LVH (↑ QRS amplitude)

  Brugada syndrome (rSR', downsloping STE V1-V2; Na channelopathy a/w SCD)

  Hyperkalemia (see below)

  Hypothermia: Osborn waves

  ⊕ deflection at J point, typically in R-precordial leads 
proportional to degree of hypothermia
- **aVR:** STE > 1 mm a/w ↑ mortality in STEMI; STE aVR > V_1 a/w left main disease
- **Early repolarization:** most often seen in V_2-V_5 in young adults (*JACC* 2015;66:470)

  1-4 mm elev of peak of notch or start of slurred downstroke of R wave (ie, J point); ± up concavity of ST & large Tw (∴ ratio of STE/T wave <25%; may disappear w/ exercise)

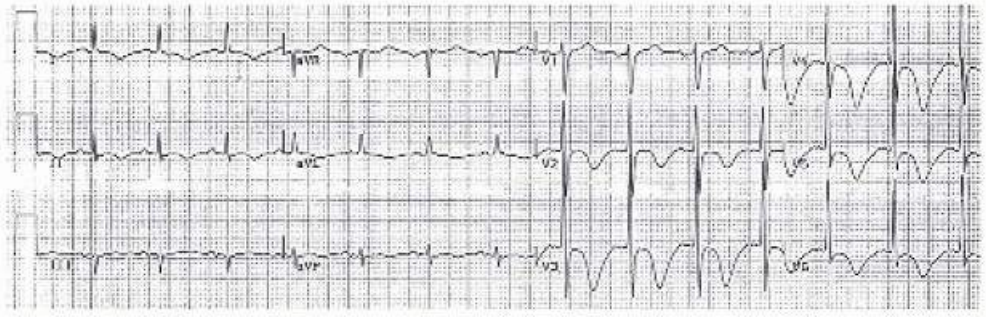
? early repol in inf leads may be a/w ↑ risk of VF (*NEJM* 2009;361:2529; *Circ* 2011;124:2208)

ST depression (STD)

- **Myocardial ischemia** (± Tw abnl) or acute true posterior MI (V_1-V_3)
- Digitalis effect (downsloping ST ± Tw abnl, does *not* correlate w/ dig levels)
- Hypokalemia (± U wave)
- Repolarization abnl in a/w LBBB or LVH (usually in leads V_5, V_6, I, aVL)

T wave inversion (TWI; generally ≥1 mm; deep if ≥5 mm) (*Circ* 2009;119:e241)

- Ischemia or infarct; *Wellens' sign* (deep, symmetric precordial TWI) → proximal LCA lesion

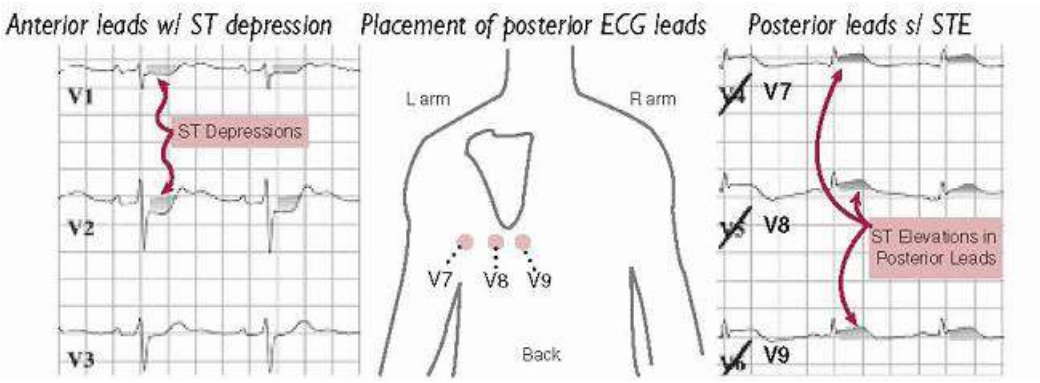


(Wellens' sign, from Cuculich PS and Kates AM. *The Washington Manual Cardiology Subspecialty Consult,* 3rd ed. Philadelphia: Wolters Kluwer Health, 2014:286.)

- Myopericarditis; CMP (Takotsubo, ARVC, apical HCM); MVP; PE (espec if TWI V_1-V_4)
- Repolarization abnl in a/w LVH/RVH ("strain pattern"), BBB
- Posttachycardia or postpacing
- Electrolyte, digoxin, PaO_2, $PaCO_2$, pH or core temperature disturbances
- Intracranial bleed ("cerebral T waves," usually w/ ↑ QT)
- Normal variant in children (V_1-V_4) and leads in which QRS complex predominantly ⊖

True posterior MI (posterior STE appearing as anterior STD)

- STD ± ↑ R wave in leads V1-V4 may correspond to acute posterior "ST-elevation" MI
- ✓ Posterior ECG leads; manage as a STEMI with rapid reperfusion



(Modified from Martindale JL, Brown DFM. *Rapid Interpretation of ECGs in Emergency Medicine*. Philadelphia:

Lippincott Williams & Wilkins, 2012:364,376)

Low voltage

- QRS amplitude (R + S) <5 mm in all limb leads & <10 mm in all precordial leads
- Etiologies: COPD (precordial leads only), pericardial effusion, myxedema, obesity, pleural effusion, restrictive or infiltrative CMP, diffuse CAD

Electrolyte Abnormalities

→ **K**	Tented Tw, ↓ QT Small Pw, ↑ PR, AVB Wide QRS → sinusoidal pattern STE (typically V_1-V_2)	
→ **K**	Flattened Tw U waves (⊕ deflection after T) ST depression Ectopy; ↑ QT & TdP	
↑ **Ca**	↓ QT, flattened Tw & Pw J point elevation	↓ **Ca**	↑ QT; Tw Δs	
(ECGs modified from Wagner GS, Strauss DG. *Marriott's Practical Electrocardiography*, 12th ed. Philadelphia: Lippincott Williams & Wilkins, 2014)

CHEST PAIN

Disorder	Typical Characteristics & Diagnostic Studies
	Cardiac Causes
ACS (15-25% of chest pain in ED)	Substernal pressure radiating to neck, jaw, arm. ± Dyspnea, diaphoresis, N/V; a/w exertion; ↓ w/ NTG or rest; however, not reliable indicator (*Annals EM* 2005;45:581). ± ECG Δs: STE, STD, TWI, Qw. ± ↑ Troponin.
Pericarditis & myo-pericarditis	Sharp pain → trapezius, ↑ w/ respiration, ↓ w/ sitting forward. ± Pericardial friction rub. ECG Δs (diffuse STE & PR ↓, opposite in aVR) ± pericardial effusion. If myocarditis, same as above + ↑ Tn and ± s/s HF and ↓ EF.

Aortic dissection	Abrupt-onset severe tearing, knifelike pain (absence ⊖ LR 0.3), ant or post midscapular. HTN or HoTN. ± Asymmetric (> 20 mmHg) BP or pulse deficit (⊕ LR 5.7), focal neuro deficit (⊕ LR >6), AI, widened mediastinum on CXR (absence ⊖ LR 0.3); false lumen on imaging. (*JAMA* 2002;287:2262)
	Pulmonary Causes
Pneumonia	Pleuritic; dyspnea, fever, cough, sputum. ↑ RR, crackles. CXR infiltrate.
Pleuritis	Sharp, pleuritic pain. ± Pleuritic friction rub.
PTX	Sudden onset, sharp pleuritic pain. Hyperresonance, ↑ BS. PTX on CXR.
PE	Sudden onset pleuritic pain. ↑ RR & HR, ↓ S_aO_2, ECG Δs (sinus tach, RAD, RBBB, $S_IQ_{III}T_{III}$, TWI V_1-V_4, occ STE V_1-V_3). ⊕ CTA or V/Q.
Pulm HTN	Exertional pressure, DOE. ↓ S_aO_2, loud P_2, RV heave, right S_3 and/or S_4.
	GI Causes
Esophageal reflux	Substernal burning, acid taste in mouth, water brash. ↑ by meals, recum-bency; ↑ by antacids. EGD, manometry, pH monitoring.
Esoph spasm	Intense substernal pain. ↑ by swallowing, ↓ by NTG/CCB. Manometry.
Mallory-Weiss	Esophageal tear precipitated by vomiting. EGD.
Boerhaave syndrome	Esoph. rupture typically precipitated by vomiting. Severe pain, ↑ w/ swallowing. Palpable SC emphysema; mediastinal air on chest CT.
PUD	Epigastric pain, relieved by antacids. ± GIB. EGD, ± *H. pylori* test.
Biliary dis.	RUQ pain, N/V. ↑ by fatty foods. RUQ U/S; ↑ LFTs.
Pancreatitis	Epigastric/back discomfort. ↑ amylase & lipase; abd CT.
	Musculoskeletal and Miscellaneous Causes
Costochond	Localized sharp pain. ↑ w/ movement. Reproduced by palpation.
Zoster	Intense unilateral pain. Pain may precede dermatomal rash.
Anxiety	"Tightness," dyspnea, palpitations, other somatic symptoms

(*Braunwald's Heart Disease*, 10th ed, 2014)

Initial approach

- **Focused history:** quality & severity of pain; location & radiation; provoking & palliating factors; intensity at onset; duration, frequency & pattern; setting in which it occurred; associated sx; cardiac hx and risk factors

Pain Feature	Classic for ACS	Atypical for ACS
Quality	Pressure (⊕ LR 1.3), tightness, "Levine" sign (clenched fist over chest), squeezing, fullness, heavy weight, more than prior angina or ≈ prior MI (⊕ LR 1.8)	Sharp (⊕ LR 0.3)
Region/radiation	Substernal, radiating to L or R arm or shoulder (⊕ LR 2.3-4.7), jaw, teeth, neck	Small area, points w/ 1 finger, radiation to back
Provocation	Exertion (⊕ LR 2.4; but may be absent)	Pleuritic, positional or w/ palp (⊕ LR ≤0.3), eating
Associated sx	Diaphoresis (⊕ LR 2.0), N/V (⊕ LR 1.9), dyspnea	

(*JAMA* 2005;294:2623)

- **Targeted exam:** VS (including BP in both arms), cardiac gallops, murmurs or rubs; signs of vascular disease (carotid or femoral bruits, ↓ pulses), signs of heart failure; lung & abdominal exam; chest wall exam for reproducibility of pain
- **12-lead ECG:** obtain w/in 10 min; c/w priors & obtain serial ECGs. In addition, consider:

  posterior leads (V_7-V_9; remove V4-V6 and place in post axillary, mid-clavic & L paraspinal position) useful to ✓ for posterior STEMI if hx c/w ACS but stnd ECG unrevealing, espec if ST ↓ V_1-V_4 (ant ischemia vs post STEMI) or R/S V_1-V_2 > 1

  R-sided leads (place V_3-V_6 in mirror image position on R side of chest) in inferior STEMI to detect RV involvement

- **CXR;** other imaging (echo, PE CTA, etc.) as indicated based on H&P and initial testing
- **Biomarkers** (see below): Tn preferred biomarker, ✓ at baseline & 3-6 h after sx onset

Biomarkers

- **Troponin:** level >99th %ile w/ rise & fall in approp. setting is dx of MI; >95% Se, 90% Sp Detectable 1-6 h after injury, peaks 24 h, may remain elevated for 7-14 d in STEMI Tn may be ↑ in CKD in absence of ACS, ∴ add CK-MB/serial Tn for confirmation *Sensitive* Tn assays: 98% Se, 90% Sp, 75% PPV, 99% NPV w/in 3 h of admit to ED, 82% Se & 95% NPV at time of admission to ED (*JAMA* 2011;306:2684)

  High-sensitivity Tn assays quantify Tn in majority of healthy individ.; prog value in asx general pop., stable CAD & DM (*NEJM* 2009;361:2538 & 2015;373:610; *JAMA* 2010;304:2503)

- **CK-MB:** less Se & Sp than Tn for dx of MI

  Sources include skeletal muscle, tongue, diaphragm, intestine, uterus, prostate

  CK-MB relative index (ratio of CK-MB to CK) >2.5-3 suggests cardiac vs skel. muscle

  CK-MB begins to rise 4-6 h post MI (may take 12 h) and returns to baseline w/in 36-48 h

  May aid in gauging timing of MI (⊕ Tn & ⊖ CK-MB suggests MI several days ago)

  May help dx reinfarction if Tn already elevated; however, Tn should ↑ as well

- Myoglobin & heart-type fatty acid binding protein are smaller molecules that may appear in circulation as early as 30 min after MI, but lack of specificity limits utility

- **D-dimer:** low level useful to r/o PE (qv) and aortic dissection (qv)

- B-type natriuretic peptide (BNP): elevations not specific for ACS but suggest ↑ ventricular wall stress seen not only in decompensated HF, but also ACS & PE

Interpretation of elevated cardiac biomarkers (troponin or CK-MB)

- *Does it reflect true myocardial injury?* Almost always the case for Tn; CK-MB less specific.

- *If myocardial injury, what is the pathobiology?* Ddx includes:

  MI (injury due to ischemia): rise and/or fall in cardiac biomarker (preferably Tn)

  >99th %ile w/ ≥1 of the following:

  1) sx of ischemia

  2) new Qw

  3) new STΔ or LBBB

  4) intracoronary thrombus

  5) imaging evidence of new loss of myocardium or regional wall motion abnl non-ischemic injury (eg, myocarditis/toxic CMP, cardiac contusion) multifactorial (eg, PE, sepsis, severe HF, renal failure, Takotsubo, infiltrative disease)

- *If* MI*, what type?* (*Circ* 2012;126:2020)

Type	Descriptor	Features
1	Spontaneous	Pathologic process in wall of coronary artery (eg, plaque rupture) resulting in intraluminal thrombus
2	Supply-demand	Mismatch due to, eg, ↑ ↑ or ↓↓ HR or BP, profound anemia or

	mismatch not due to Δ in CAD	hypoxemia, coronary vasospasm, HCM, severe AS
3	Sudden cardiac death	
4a	Related to PCI	Tn >5x 99th %ile or >20% rise if already elevated +≥1 MI clinical/imaging criteria above
4b	Stent thrombosis	
5	Related to CABG	Tn > 10x 99th %ile + new Qw or LBBB, angio confirmation, or new wall motion abnl

- Classification important as antithrombotic Rx relevant for type 1 but not type 2 MI, whereas anti-ischemic Rx (↑ O_2 supply & ↓ demand) particularly important for type 2

Early noninvasive imaging (also see noninvasive evaluation of CAD)

- If low prob of ACS (eg, ⊖ ECG & Tn) & stable → noninvasive fxnal or imaging test
- Treadmill electrocardiography: can be performed after 6-8 h of evaluation
- Radionuclide imaging in Pts who cannot exercise or have uninterpretable ECG
- Can perform acute rest perfusion imaging if ongoing or recent (w/in 2 h) pain (⊖ scan r/o ischemia; ⊕ scan could represent ischemia or infarct, need pain-free rest images)
- Echo (w/ or w/o stress) to assess for regional wall motion abnl; interpretation difficult in those w/ h/o prior MI
- Coronary CT angio (CCTA): NPV 98% for signif CAD, but PPV 35% for ACS; helpful to r/o CAD if low-intermed prob of ACS. CCTA vs noninvasive fxnal test for ischemia → ↓ time to dx & LOS, but ↑ probability of cath/PCI, contrast exposure & ↑ radiation (*NEJM* 2012;366:1393 & 367:299; *JACC* 2013;61:880)
- "Triple r/o" CT angiogram for CAD, PE, AoD

NONINVASIVE EVALUATION OF CAD

Stress testing (*Circ* 2007;115:1464; *JACC* 2012;60:1828)

- **Indications:** dx CAD, evaluate Δ in clinical status in Pt w/ known CAD, risk stratify s/p ACS, evaluate exercise tolerance, localize ischemia (imaging required)
- **Contraindications** (*Circ* 2002;106:1883; & 2012;126:2465)

  Absolute: AMI w/in 48 h, high-risk UA, acute PE, severe sx AS, uncontrolled HF, uncontrolled arrhythmias, myopericarditis, acute aortic dissection

  Relative: left main CAD, mod valvular stenosis, severe HTN, HCMP high-degree AVB, severe electrolyte abnl

Exercise tolerance test

- Generally preferred if patient can exercise to a meaningful level; Se ˜65%, Sp ˜80%
- Typically via treadmill

Protocol	Description
Standard Bruce	↑ speed & incline q3min until 85% max predicted HR or sxs
Modified Bruce	Adds two stages at start that require less work than standard Bruce stage 1; consider in sedentary/deconditioned Pt
Submaximal	Stop earlier (eg, 70% max predicted HR or 5 METs or any anginal sx); consider if recent MI

- Stationary cycle or arm ergometry (lower max workload) if Pt cannot walk
- Hold anti-ischemic meds (eg, nitrates, βB, CCB, ranolazine) if trying to dx obstructive CAD, but continue meds when assessing if Pt ischemic on current med regimen

Pharmacologic stress test (nb, requires imaging as ECG not interpretable)

- Use if unable to exercise, low exerercise tolerance, or recent MI. Se & Sp ≈ exercise.
- Preferred if LBBB or V-paced, as higher prob of false ⊕ exercise imaging (typically reversible or fixed anteroseptal defect).
- **Coronary vasodilator:** diffuse coronary arteriolar vasodilation → relative "coronary steal" from vessels w/ fixed epicardial disease. Reveals CAD, but *not* if Pt *ischemic* w/ *exercise.* Options include:

  Adenosine or dipyridamole (↑ adenosine reuptake). Side effects: flushing, bradycardia & AVB, dyspnea & bronchospasm.

  Selective A2A receptor agonist (eg, regadenoson): less flushing, dyspnea, bronchospasm

  Longer half-life of dipyridamole & regadenoson allow to be combined w/ exercise

  Avoid caffeine (adenosine receptor antagonist) w/in 12 h of test. Conversely, can use aminophylline to reverse effects of these agents.

  Contraindic: HoTN, sick sinus, high-degree AVB, bronchospasm (selective agents safer)
- **Chronotropes/inotropes** (more physiologic): dobutamine (may precip tachyarrhythmia)

Imaging for stress test (see Photo Inserts)

- Use if uninterpretable ECG (V-paced, LBBB, resting ST ↑ >1 mm, digoxin, LVH, WPW), after indeterminate ECG test, or if pharmacologic test
- Use when need to localize ischemia (often used if prior coronary revasc)
- Ideally use exercise as stress modality rather than pharmacologic
- **Radionuclide myocardial perfusion imaging** w/ images obtained at rest & w/ stress

  SPECT (eg, ^{99m}Tc-sestamibi): Se ~85%, Sp ~80%

  PET (rubidium-82): Se ~90%, Sp ~85%

ECG-gated imaging allows assessment of LV fxn (including regional systolic wall thickening or lack thereof as a sign of ischemia/infarction)

- **Echo** (exercise or dobuta): Se ~85%, Sp ~85%; no radiation; operator dependent
- Cardiac MRI (w/ pharmacologic stress) another option with excellent Se & Sp

Test results

- **HR** (must achieve ≥85% of max pred HR [220 - age] for *exer.* test to be dx), **BP** response, peak **double product** (HR × BP; nl >20k), HR recovery (HR_{peak} - $HR_{1\ min\ later}$; nl > 12)
- **Max exercise capacity** achieved (METS or min)
- Occurrence of **symptoms** (at what level of exertion and similarity to presenting sx)
- **ECG Δs:** *downsloping* or *horizontal* ST ↓ (≥1 mm) 80 ms after QRS predictive of CAD upsloping ST ↓ w/ rapid return to baseline usually due to ↑ HR & atrial repol artifact lead V_5 most sensitive; Δs isolated to inferior leads may be artifact location of ST ↓ does *not* localize ischemic territory

  STE: highly predictive of CAD & localizes; in aVR suggests LM CAD; nonspecific if in leads w/ prior Qw
- **Duke treadmill score** = exercise min - (5 × max ST dev) - (4 × angina index) [angina index = 0 none, 1 nonlimiting sxs, 2 limiting sxs]

Category	CAD	1-y mort	5-y survival
Low risk (≥5)	60% w/o signif stenosis	<1%	97%
Moderate risk (-10 to 4)	31% w/ 3VD or LM	2-3%	90%
High risk (≤-11)	74% w/ 3VD or LM	≥5%	65%

- **Imaging:** radionuclide defects or echocardiographic regional wall motion abnormalities reversible defect = ischemia; fixed defect = infarct; transient isch dilation = severe CAD false ⊕: breast → ant "defect" and diaphragm → inf "defect" false ⊖ may be seen if balanced (eg, 3VD) ischemia (global ↓ perfusion w/o regional Δs)

High-risk test results

- ECG: ST ↓ ≥2 mm *or* ≥1 mm in stage 1 *or* in ≥5 leads *or* ≥5 min in recovery; STE; VT
- Physiologic: ↓ or fail to ↑ BP, <4 METS, angina during exercise, Duke score ≤ -11; ↓ EF
- Radionuclide: ≥1 lg or ≥2 mod. reversible defects, transient LV cavity dilation, ↑ lung uptake
- High-risk test has PPV ~50% for LM or 3VD, ∴ consider coronary angio

Myocardial viability (*Circ* 2008;117:103; *Eur Heart J* 2011;31:2984 & 2011;32:810)

- Viable myocardium = dysfxn at rest, but not scarred and has potential for recovery
- Goal: identify hibernating or stunned myocardium that could regain fxn after revasc

Viability Test	Sens	Spec	Mechanism
MRI	~85%	~75%	Assesses cellular integrity
PET	~90%	~65%	Assesses cell metabolism
Dobut stress echo	~80%	~80%	Assesses contractile reserve
Myocard contrast echo	~85%	~50%	Assesses cellular integrity
Thallium: rest-redistrib or stress-reinjection	~85%	~55%	Assesses cellular integrity (K^+ analogue taken up by Na/K-ATPase)
Technetium-MIBI	~85%	~65%	Assesses cellular integrity (requires intact mitochondria)

- However, in Pts w/ ↓ EF, presence of viability did not identify differential clinical benefit from CABG vs med Rx (*NEJM* 2011;364:1617)

Coronary CT angio (CCTA; *NEJM* 2008;359:2324; *Circ* 2010;121:2509)

- High NPV to r/o CAD, but low PPV
- In Pts presenting with CP, presence of plaque sensitive (100%) but not specific (54%) for ACS, ∴ NPV 100%, PPV 17% (*JACC* 2009;53:1642). CCTA vs noninvasive fxnal test for ischemia → ↓ time to dx & LOS, but ↑ probability of cath/PCI, contrast exposure & ↑ radiation (*NEJM* 2012;366:1393 & 367:299; *JACC* 2013;61:880).
- In sx outPt, CCTA vs fxnal testing led to more radiation, coronary angiography & revascularization, but no difference in clinical outcomes (PROMISE *NEJM* 2015;372:1291)
- CCTA images may be limited if: HR >60-70 bpm, irregular rhythm, calcium deposition or stents (may create artifact), inability to breath hold 5 sec, vessel diameter < 1.5 mm. Image quality best at slower & regular HR (? give βB if possible, goal HR 55-60).
- Useful for assessing patency of bypass grafts

MRI angiography (*Lancet* 2012;379:453)

- Unlike CCTA, does not require iodinated contrast, HR control or radiation exposure. Can also assess LV fxn, enhancement (early = microvasc obstruction; late = MI). Limitations: cost, operator-dependent, long duration, ↓ spatial resolution.
- In head-to-head comparisons, CMRI and CCTA appear to have grossly comparable sensitivity and specificity (*JACC* 2005;46:92; *Annals* 2006;145:207)

Coronary artery calcium score (*NEJM* 2012;366:294; *JAMA* 2012;308:788)

- Quantifies extent of calcium; thus *estimates* plaque burden (but *not* % coronary stenosis)
- Compared w/ CCTA, CAC score assessment requires lower radiation exposure (1-2 mSv)
- CAC sensitive (91%) but not specific (49%) for presence of CAD; high NPV to r/o CAD

CAC Score	Suggested plaque burden
0	No disease
1-99	Mild disease
100-399	Moderate disease
>400	Severe disease

- ? value as screening test to r/o CAD in sx Pt (CACS <100 → 3% probability of signif CAD; but interpretation affected by age, gender)
- May provide incremental value to clinical scores for risk stratification (*JAMA* 2004;291:210). ACC/AHA guidelines note CAC assessment is reasonable in asx Pts w/ intermed risk (10-20% 10-y Framingham risk; ? value if 6-10% 10-y risk) (*Circ* 2010;122:e584).

STABLE ISCHEMIC HEART DISEASE

Epidemiology is U.S. (*Circ* 2015;131:e29)

- Prevalence: 20-39 y: <1%; 40-59 y: 5-6%; 60-79 y: 21% in ♂ & 11% in ♀; ≥80 y: 35% in ♂ & 19% in ♀; lifetime risk after age 40: 50% in men & 32% in women
- Ischemic heart disease (IHD) remains leading cause of death in both men & women

Workup (*Circ* 2012;126:e354)

- Initiate workup if suspected new dx of IHD or Δ in clinical status
- H&P, ECG (looking for ischemic or prior infarct Δs such as Qw, PRWP, ST or Tw abnl)

Pretest Likelihood of CAD (%) (*NEJM* 1979;300:1350; *Annals* 1993;118:81)

	Nonanginal (≤1 sx)		Atypical angina (2 sx)		Typical angina (all 3 sx)	
Age	Men	Women	Men	Women	Men	Women
35	3↔ 35	1 ↔ 19	8 ↔ 59	2 ↔ 39	30 ↔ 88	10 ↔ 78

45	9 ↔ 47	2 ↔ 22	21 ↔ 70	5 ↔ 43	51 ↔ 92	20 ↔ 79
55	23 ↔ 59	4 ↔ 21	45 ↔ 79	10 ↔ 47	80 ↔ 95	38 ↔ 82
65	49 ↔ 69	9 ↔ 29	71 ↔ 86	20 ↔ 51	93 ↔ 97	56 ↔ 84

Classic angina sx: substernal chest pain, provoked by exertion, relieved by rest or NTG. W/in each cell, 1st # is % for Pt w/o risk factors; 2nd is for Pt w/ DM, smoking, & hyperchol.

- **Noninvasive testing** (qv) if intermediate risk (ie, >10-20% & <80-90%). If Pt has low prob, then ↑ risk false ⊕; if very high prob, ⊖ test does not adeq r/o CAD, ∴ consider cor angio.
- **Coronary angio** if: high-risk noninv results (qv); very high pretest prob; refract angina; uncertain dx after noninvasive testing (& compelling need to determine dx), occupational need for definitive dx (eg, pilot) or inability to undergo noninvasive testing; survivor of SCD or life-threatening vent. arrhythmia; unexplained heart failure or ↓ EF; suspected spasm or nonatherosclerotic cause of ischemia (eg, anomalous coronary)

Optimal medical therapy (OMT) (*Circ* 2012;126:e354 & 2014;130:1749; HTN 2015;65:1372)

- **ASA** 75-162 βg/d; **βB** for 3 y post MI or if ↓ EF; **statin** (typically high intensity; see "Lipids")
- **ACEI** (or ARB) if HTN, DM, CKD or ↓ EF
- Risk factor targets: BP <140/90 (consider <130/80 if prior MI), Hb_{A1c} 7-9% (<7% if long life expect.), BMI 18.5-24.9 kg/m^2
- Smoking cessation; influenza vaccine
- Diet: ↑ veg, fruits, whole grains; ↓ sweets, sugar-sweetened bevs & red meat; sat fat 5-6% total cals, *trans* fat <1% total cals, chol <200 mg/d; Na ≤2400 mg/d (ideally ≤1500 mg/d)
- Exercise: ˜40 min moderate-to-vigorous physical activity 3-4x/wk

Medical therapies for symptomatic relief (*Circ* 2012;126:e354)

- **Beta blockers** 1st-line therapy
- **CCB** (verap/dilt or long-acting dihydro) or **long-acting nitrates:** add-on or if βB intolerant
- **Ranolazine** (↓ late inward Na+ current to ↓ myocardial demand): add-on or if βB intolerant

Coronary revascularization (*Circ* 2011;124:e574)

- If unacceptable angina despite max tolerated med Rx or if potential to improve survival
- OMT should be initial focus if stable & w/o critical anatomy & w/ normal EF
- Older studies showed survival benefit w/ revasc (CABG) vs med Rx (pre-statin era) if:

  LM (≥50% stenosis), 3VD (≥70% stenoses) espec if ↑ EF, 2VD w/ critical prox LAD, ? 1-2 VD w/ large area of viable, ischemic myocardium

Recent Studies of Revascularization in Modern Era of OMT

Compare	Trial	Pts	Result
PCI vs OMT	COURAGE[a]	1-3VD, EF >30%	PCI does *not* ↓ D/MI; faster sx resolution
	FAME-II[b]	≥1VD w/ FFR (qv) ≤0.8	PCI ↑ peri-PCI MI, but then 44% ↓ death/spont MI; ? greater benefit if FFR <0.65
CABG vs OMT	STITCH[c]	EF ≤35% (majority w/ 3VD)	CABG 20% ↓ CV death, no Δ in all-cause mortality
CABG vs PCI	SYNTAX[d]	3VD or LM	CABG ↓ D/MI & revasc but ± ↑ stroke High SYNTAX/SYNTAX II score[g] ID's those who benefit most from CABG
	PRECOMBAT[e]	LM	PCI ? noninferior but ↑ repeat revasc
	FREEDOM[f]	DM w/ ≥2VD	CABG ↓ D/MI, but ↑ stroke

[d] *Lancet* 2013;381:629 & 639;

[e] *NEJM* 2011;364:1718;

[f] *NEJM* 2012;367:2375;

[g] www.syntaxscore.com

- LM or 3VD: CABG, espec if ↑ EF or DM; consider PCI if SYNTAX score ≤22 & high surg risk
- 2VD w/ prox LAD, ↓ EF, or extensive ischemia: CABG (espec if DM) or ? PCI
- ? 1VD (low FFR) w/ prox LAD + either ↓ EF or extensive ischemia: PCI or CABG (w/ LIMA)
- Exp't device to narrow coronary sinus ↓ angina (*NEJM* 2015;372:517)

LIPID DISORDERS

Measurements

- Lipoproteins = lipids (cholesteryl esters & triglycerides) + phospholipids + proteins include: chylomicrons, VLDL, IDL, LDL, HDL, Lp(a)
- Measure after 12-h fast; LDL is typically calculated w/ Friedewald equation:

  LDL-C = TC - HDL-C - (TG/5) [last term assumes TG:VLDL ratio = 5:1]; underestim. if TG >400 or LDL-C <70 mg/dL (*JAMA* 2013;310:2061); ∴ directly measure LDL-C

  Non-HDL-C (TC - HDL-C) and apoB are alternative nonfasting measures of risk

  Lipid levels stable up to 24 h after ACS and other acute illnesses, then ↓ and may take 6 wk to return to nl
- Metabolic syndrome (≥3 of following): waist ≥40" (♂) or ≥35" (♀); TG ≤150; HDL <40 mg/dL (♂) or <50 mg/dL (♀); BP ≤130/85 mmHg; fasting glc ≤100 mg/dL (*Circ* 2009;120:1640)
- Lp(a) = LDL particle bound to apo(a) via apoB; genetic variants a/w MI (*NEJM* 2009;361:2518)

Primary dyslipidemias

- Familial hypercholesterolemia (FH, 1:500): defective LDL receptor; ↑ ↑ chol, nl TG; ↑ CAD
- Familial defective apoB100 (1:1000): similar to FH
- Familial combined hyperlipidemia (1:200): polygenic; ↑ chol, ↑ TG, ↓ HDL; ↑ CAD
- Familial dysbetalipoproteinemia (1:10,000): ↑ chol & TG; xanthomas; ↑ CAD
- Familial hypertriglyceridemia (FHTG, 1:500): ↑ TG, ± ↑ chol, ↓ HDL, pancreatitis

Secondary Dyslipidemias

Category	Disorders
Endocrinopathies	Type 2 diabetes (↑ TG, ↓ HDL); lipodystrophy (↑ TG) Hypothyroidism (↑ LDL, ↑ TG); hyperthyroidism (↓ LDL) Cushing's syndrome & exogenous steroids (↑ LDL, ↑ TG)
Renal diseases	Renal failure (↑ LDL, ↑ TG); nephrotic syndrome (↑ LDL, ↑ TG)
Hepatic diseases	Cholestasis, PBC (↑ LDL); liver failure (↓ LDL); acute hepatitis (↑ TG)
Lifestyle	Obesity, sat & trans fat (↑ TG, ↓ HDL, ↑ LDL); sedentary lifestyle (↓ HDL); alcohol (↑ TG, ↑ HDL); tobacco (↓ HDL); anorexia (↑ LDL); very low-fat diet, high-refined-carb diet (↑ TG); preg (↑ LDL; ↑ TG)
Medications	Thiazides (↑ LDL, ↑ TG); βB (except carvedilol, ↑ TG, ↓ HDL); protease inhib (↑ TG); estrogens (↑ TG, ↑ HDL); androgens (↓ HDL); cyclosporine, amiodarone (↑ LDL); bile acid sequestrants, protease inhib, retin. acid, sirolimus, raloxifene, tamoxifen (↑ TG)

Physical exam findings

- Tendon xanthomas: seen on Achilles, elbows and hands; implies LDL >300 mg/dL
- Eruptive xanthomas: pimple-like lesions on extensor surfaces; implies TG >1000 mg/dL
- Xanthelasma: yellowish streaks on eyelids seen in various dyslipidemias
- Corneal arcus: common in older adults, imply hyperlipidemia in young Pts

Drug Treatment

Drug	↓ LDL	↑ HDL	↓ TG	Side effects/comments
Statins	20-60%	5-10%	10-25%	Doubling of dose → 6% further ↓ LDL. ↑ ALT in 0.5-3% (dose-dependent); ✓ before starting and then after as clinically indicated Myalgias <10% (not always ↑ CK), myositis 0.5%, rhabdo <0.1%, risk dose-dependent ↑ risk of DM (may be related to LDL-R; *JAMA* 2015;313:1029); screen if risk factors
Ezetimibe	15-20%	—	—	Well tolerated; typically w/ statin
Fibrates	5-15%	5-15%	35-50%	Myopathy risk ↑ w/ statin (gemfibrozil > fenofibrate). Dyspepsia, gallstones, ↑ Cr. ✓ renal fxn at baseline, 3 mo, q6mo.
Niacin	10-25%	~30%	40%	Flushing (less w/ sustained release; ASA preRx may ↓), hyperglycemia, ↑ UA. ✓ renal fxn, UA, glc ± HbA1c at baseline and q6mo or w/ uptitration.
Resins	20%	3-5%	↑	Bloating, binds other meds
Ω-3 FA	5% ↑	3%	25-50%	Dyspepsia, diarrhea, skin Δs, bleeding
PCSK9 inhibitors	40-65%	5-10%	15-25%	mAb inj SC q2w or q4w (*Lancet* 2012;380:2007 & *JACC* 2015;65:2638)
CETP inhibitors	~30%	140%	5-10%	*Investigational* (*NEJM* 2010;363:2406; *Lancet* 2015;386:452)

Treatment of LDL-C (*Lancet* 2014;384:607)

- **Statins:** every 1 mmol (39 mg/dL) ↓ LDL-C → 22% ↓ major vascular events (CV death, MI, stroke, revasc) in individuals w/ & w/o CAD (*Lancet* 2010;376:1670); ∴ *mainstay of therapy as potent, safe and well-tolerated*

- Consistent CV benefit even in individuals starting w/ LDL-C ≤60 mg/dL (*JACC* 2011;57:1666)
- No clear evidence to date to suggest any harm from achieving very low LDL-C levels
- Elevated hs-CRP *may* identify Pts who derive ↑ benefit (*NEJM* 2001;344:1959 & 2008;359:2195)
- Similar clinical benefit also seen w/ some older nonstatin Rxs (resins, fibrates, niacin) when sufficiently lowered LDL-C (*JACC* 2005;46:1855)
- **Ezetimibe:** ↓ major vascular events incl MI & stroke when added to statin post-ACS, w/ magnitude of benefit consistent w/ LDL-statin relationship (IMPROVE-IT, *NEJM* 2015;372:2387)
- **PCSK9 inhibitors:** ˜60% ↓ LDL on top of statin, as monoRx, and in FH (*EHJ* 2014;35:2249); prelim data w/ encouraging ↓ CV outcomes (*NEJM* 2015;372:1500), definitive trials ongoing

Treatment of HDL-C (*Lancet* 2014;384:618)

- Low levels of HDL-C associated with ↑ risk of MI
- However, Mendelian randomization studies do not support causal role (*Lancet* 2011;380:572)
- **Niacin:** in Pts w/ well-controlled LDL-C (<80 mg/dL) on a statin, minimally ↓ LDL, modestly ↑ HDL, and did not ↑ CV events (*NEJM* 2011;365:2255 & 2014;371:203)
- **CETP inhibitors:** one that ↑ HDL-C by 25% did not lead to clinical benefit in Pts w/ well-controlled LDL-C on a statin (*NEJM* 2012;367:2089); CV outcomes trials of inhibitors that ↑ HDL-C by 140% *and* ↑ LDL-C by ˜30% ongoing (*NEJM* 2010;363:2406; *JAMA* 2011;306:2099)

Treatment of hypertriglyceridemia (*Lancet* 2014;384:626)

- Reasonable to treat very high levels (>500- 1000 mg/dL) to ↓ risk of pancreatitis
- High levels of TG associated with ↑ risk of MI, but whether causal remains debated
- **Fibrates** (gemfibrozil & fenofibrate): mixed data in terms of ↑ vascular events, ? greater benefit if high TG (*Circ* 1992;85:37; *NEJM* 1999;341:410; *Lancet* 2005;366:1849; *NEJM* 2010;362:1563)
- **Fish oil** (containing Ω-3 fatty acids EPA & DHA): recent meta-analyses suggest supplementation w/o meaningful effect on CV events (*JAMA* 2012;308:1024)
- APOC3 inhibitors under study and ↑ TG by up to ˜70% (*NEJM* 2015;373:438)

Treatment of Lp(a)

- Consider ↓ to <50 mg/dL w/ niacin in intermed- to high-risk Pts (*EHJ* 2010;31:2844-53); however, benefit unclear espec if LDL-C well controlled (*JACC* 2014;63:520)

Guidelines (*Circ* 2014;129(Suppl 2):S1)

- Focus now on statin strategies, rather than achieving LDL-C goals
- Clinical atherosclerotic CV disease (ASCVD) includes h/o ACS, stable angina, arterial revasc, stroke, TIA, or PAD presumed to be of atherosclerotic origin
- 10-y CV Risk Score for CHD or stroke based on age, sex, race, SBP, TC, LDL, DM, tobacco, BP Rx; http://my.americanheart.org/cvriskcalculator
- Additional risk factors to consider include: LDL-C ≥160 mg/dL, genetic hyperlipid., FHx premature ASCVD, hsCRP >2 mg/L, CAC score ≥300 or ≥75th %ile, ABI <0.9.

2013 ACC/AHA Guideline of Treatment of Blood Cholesterol

Population	10-y CV risk	Statin Recommendation
Clinical ASCVD (ie, 2° prevention)	n/a	High intensity. If age >75 y, eval risk-benefit for high vs moderate intensity
LDL-C ≥190 mg/dL	n/a	High intensity
DM (type 1 or 2); age 40-75 y	≥7.5%	High intensity
	<7.5%	Moderate intensity
Age 40-75 y (and none of the above)	≥7.5%	High or moderate intensity
	5-<7.5%	Reasonable to offer moderate intensity
	<5%	Consider statin if additional risk factor

- If statin intolerant or LDL-C remains elevated despite high-intensity statin (as well as reinforcement of med adherence, lifestyle changes and exclusion of 2° causes of dyslipidemia) nonstatin LDL-lowering therapies remain reasonable
- If Pt does not tolerate high-intensity statin, consider dose reduction before d/c statin

Statin Doses & LDL-C Reduction

Intensity	↓ LDL-C	Rosuva	Atorva	Simva	Prava	Lova	Fluva	Pitava
High	≥50%	20-40	40-80	(80)				
Mod	30-50%	5-10	10-20	20-40	40-80	40	80	2-4
Low	<30%			10	10-20	20	20-40	1

Doses are in mg. Simva 80 mg has ↑ myopathy risk and should not be used unless dose already tolerated >12 mo.

ANGIOGRAPHY, PCI, & CABG

Precath checklist

- Document peripheral arterial exam (radial, femoral, DP, PT pulses; bruits); if plan for radial artery access, ✓ palmar arch intact (eg, w/ pulse oximetry & plethysmography), although value remains unproven (*JACC* 2014;63:1833)
- Ensure Pt can lie flat for several hours
- ✓ CBC, PT-INR (ideally ≤1.5), & Cr; blood bank sample
- NPO >6 h; IVF if appropriate (± bicarb; acetylcysteine no longer rec; see "CIAKI")

Vascular access

- Femoral artery commonly used; high puncture ↑ risk of retroperitoneal bleed; low puncture ↑ risk of peripheral arterial complic.; can access a synthetic graft if a few months old
- Radial artery: 33% ↓ major bleeding, trend to 15% ↓ in MACE & 28% ↓ mortality, espec if >80% of cases at center done radially (*Lancet* 2015;385:2465)

Periprocedural pharmacotherapy for PCI

- **Aspirin:** 325 mg × 1 (≥2 h prior to angio) → 81 mg qd
- **$P2Y_{12}$ inhibitor** *(choose one):*

  clopidogrel: 600 mg × 1 → 75 mg qd; preRx ↓ MACE (*JAMA* 2005;294:1224 & 2012;308:2507) prasugrel or ticagrelor (only in ACS, qv)

  cangrelor (IV, short-acting): ↓ early ischemic events vs clopi given w/o preload (*NEJM* 2013;368:1303)
- **GP IIb/IIIa inhibitor:** *consider adding* abciximab, eptifibatide, or tirofiban; data showing ↓ MACE largely before routine $P2Y_{12}$ inhibition and w/ UFH as anticoagulant. Remains reasonable espec if using clopidogrel and did not preRx.
- **Anticoagulant** *(choose one; typically* d/c'd *at end of* PCI*):*

  UFH: most common choice in U.S.

  bivalirudin: ↓ bleeding (espec vs UFH + GP IIb/IIIa inhib; *JAMA* 2015;313:1336), ± ↑ MI, ↑ stent thrombosis in STEMI (not mitigated by longer infusion), ↑ mortality in some but not all trials (*Lancet* 2014;384:599; MATRIX *NEJM* 2015); use if Pt has HIT enoxaparin (nb, cannot ✓ degree of anticoag)
- **Statin** (high-dose): PreRx ↓ peri-PCI myonecrosis (*Circ* 2011;123:1622) & ↓ risk of contrast-induced nephropathy (*JACC* 2014;63:71)

PCI options

- **Balloon angioplasty (POBA):** effective, but c/b dissection & elastic recoil & neointimal hyperplasia → restenosis; now reserved for small lesions & ? some SVG lesions
- **Bare metal stents (BMS):** ↓ elastic recoil → 33-50% ↓ restenosis & repeat revasc (to ˜10% by 1 y) c/w POBA; requires $P2Y_{12}$ inhibitor ≥4 weeks (ideally up to 6 mo)
- **Drug-eluting stents (DES)**

antiproliferative drug released over several weeks → ↓ neointimal hyperplasia ~75% ↓ restenosis, ~50% ↓ repeat revasc (to <5% by 1 y), no Δ D/MI (*NEJM* 2013;368:254)

delayed re-endothelialization & potentially proinflammatory polymers may cause ↑ in risk of late stent thrombosis; requires $P2Y_{12}$ inhibitor ≥6 mo

next generation DES (eg, w/ everolimus) w/ *lower* risk of stent thrombosis vs BMS (*Lancet* 2012;379:1393)

Other peri-PCI interventions

- **Fractional flow reserve (FFR):** ratio of max flow (induced by IV or IC adenosine) distal vs proximal to a stenosis; if used to guide PCI (ie, revasc only if FFR <0.8) → ↓ # stents & ↓ D/MI/revasc (*NEJM* 2009;360:213)
- Thrombus aspiration: small study showed manual aspiration of thrombus pre-PCI in STEMI ↓ mortality, but larger studies show no benefit and ↑ stroke (*Lancet* 2008;371:1915; *NEJM* 2013;369:1587 & 2015;372:1389)

Post-PCI complications

- Postprocedure ✓ vascular access site, distal pulses, ECG, CBC, Cr
- Vascular closure devices speed time to hemostasis and ↓ incidence of hematoma (*JAMA* 2014;312:1981)
- **Bleeding**

  hematoma/overt bleeding: **manual compression,** reverse/stop anticoag

  retroperitoneal bleed (if puncture above inguinal ligament)

  may p/w ↓ Hct ± flank or back pain; ↑ HR & ↓ BP late

  Dx w/ abd/pelvic CT (I^-)

  Rx: reverse/stop anticoag (d/w interventionalist), IV fluids/PRBC/plts as required; if bleeding uncontrolled, consult performing interventionalist or surgery

- **Vascular damage** (~1% of dx angio, ~5% of PCI; *Circ* 2007;115:2666)

  pseudoaneurysm: hematoma w/ continued communication to artery can present w/ triad of pain, expansile mass, systolic bruit; diagnose w/ U/S;

  Rx (if *pain* or >2 cm): U/S-directed thrombin injection (>95% success, depends on anatomy); surgical repair if very large or if minimally invasive Rx fails

  AV *fistula:* continuous bruit; Dx: U/S; Rx: surgical repair

  limb ischemia (emboli, dissection, clot): cool, mottled extremity, ↓ distal pulses; Dx: pulse volume recording (PVR), angio; Rx: percutaneous or surgical repair
- **Peri-PCI MI:** >5× ULN of Tn/CK-MB + either sx or ECG/angio/imaging Δs; Qw MI in <1%
- **Renal failure:** contrast-induced manifests w/in 24 h, peaks 3-5 d (see "CIAKI")
- **Cholesterol emboli syndrome**

  typically seen in middle-aged & elderly and w/ heavy burden of aortic atheroma multiple clinical manifestations (although may be delay between cath & s/s) including: intact distal pulses but livedo reticularis pattern and toe necrosis ("blue toe syndrome") renal failure: late and progressive (thus unlike CIAKI), ± eos in urine mesenteric ischemia: abd pain, GIB, pancreatitis

CNS: TIA, stroke, amaurosis fugax, Hollenhorst plaques (bright retinal lesion)

Dx: can only be confirmed by biopsy; may see ↑ circulating eos, ↓ complement, ↑ CRP, ↑ ESR, ↑ plts, ↑ fibrinogen

Rx: supportive; no clear benefit for anti-inflam or anticoagulant Rx

- **Stent thrombosis** (acute clot formation in stent): rare event, but high mortality can occur anytime between mins to yrs after PCI typically p/w ACS (often STEMI)

  typically due to either **mechanical problem** (stent underexpansion or unrecognized dissection, typically presents early) or **d/c of antiplt Rx** (espec if d/c both ASA & $P2Y_{12}$ inhib; *JAMA* 2005;293:2126)

- **In-stent restenosis** (neointimal hyperplasia): months after PCI, typically p/w gradual ↑ angina (10% p/w ACS). Due to combination of elastic recoil and neointimal hyperplasia; ↓ w/ DES vs BMS.

Duration of $P2Y_{12}$ inhibition

- In Pts w/ MI (qv), goal of antiplatelet therapy is ↑ CVD, MI, and stroke as well as rarer event of stent thrombosis. ∴ Long-term therapy *beyond* 12 mo is logical and has been shown to ↓ CV death, MI, and stroke (*NEJM* 2015;372:1791; *JACC* 2007;49:1982 & 2015;65:2211).
- In Pts w/ SIHD, concern for late (>30 d) stent thrombosis led to recs for 12-mo duration, but newer generation stents have lower risk of stent thrombosis
- Several small trials showed shorter duration of $P2Y_{12}$ inhibition (3-6 vs 12 mo) led to nonstatistically significant higher rates of MI and ST (but still infrequent) but less bleeding (*JACC* 2012;60:1340; *JAMA* 2013;310:2510; *EHJ* 2015;36:1252)
- Much larger DAPT trial showed that longer inhibition (30 vs 12 mo) led to 29% ↓ MACE and 71% ↓ ST (although rates and absolute risk reduction very low with newer generation stents), but ↑ bleeding and, in Pts w/ SIHD, marginally significant ↑ mortality (driven by non-CV mortality) (*NEJM* 2014;371:2155)

Need for premature discontinuation of antiplatelet therapy

- If possible, postpone major invasive procedures ≥1 mo after BMS or ≥3-6 mo after DES
- If not possible and high of risk bleeding during procedure, d/c prasugrel 7 d, clopidogrel 5 d, or ticagrelor 5 d (per prescribing information, but in major clinical trial, just ~3 d) prior to procedure. Continue ASA and resume $P2Y_{12}$ inhibitor w/ loading dose ASAP per surgery.
- If high-risk stent and bridging required, consider short-acting GP IIb/IIIa inhibitor (eptifi-batide or tirofiban) from 3 d until 4-6 h prior to surgery (*Circ* 2013;128:2785). Consider cangrelor (IV reversible $P2Y_{12}$ inhib) (*JAMA* 2012;307:265).

Advances in CABG technique

- **"Mini-CABG"** = minimally invasive. Thoracotomy or partial sternotomy rather than full sternotomy. Advantages include ↓ pain & ↓ LOS. May be on- or off-pump.
- **Off-pump** ("beating heart surgery"): avoids cardiopulmonary bypass but makes anastomotic suturing more challenging. In 1 study, ↑ CV death and ↓ graft patency at 12 mo c/w on-pump (*NEJM* 2009;361:1827); other studies w/ ≈ mortality w/ off- vs on-pump.
- **Robotic:** type of mini-CABG where endoscopic instruments inserted via small incisions to anastomose the

LIMA to the LAD on closed chest and beating heart

- **Hybrid procedures:** typically involves combo of LIMA-LAD mini-CABG with PCI of other vessels

ACUTE CORONARY SYNDROMES

Spectrum of Acute Coronary Syndromes

Dx	UA	NSTEMI	STEMI
Coronary thrombosis	Subtotal occlusion		Total occlusion
History	angina that is new-onset, crescendo or at rest; usually <30 min		angina at rest
ECG	± ST depression and/or TWI		ST elevations
Troponin/CK-MB	⊖	⊕	⊕⊕

Ddx (causes of myocardial ischemia/infarction other than atherosclerotic plaque rupture)

- **Nonatherosclerotic coronary artery disease**

  Spasm: Prinzmetal's variant, cocaine-induced (6% of CP + cocaine use r/i for MI)

  Dissection: spontaneous (vasculitis, CTD, pregnancy), aortic dissection with retrograde extension (usually involving RCA → IMI) or mechanical (catheter, surgery, trauma)

  Embolism (*Circ* 2015;132:241): AF, thrombus/myxoma, endocard., prosth valve; thrombosis

  Vasculitis: Kawasaki syndrome, Takayasu arteritis, PAN, Churg-Strauss, SLE, RA

  Congenital: anomalous origin from aorta or PA (coronary compressed), myocardial bridge (intramural segment)

- **Ischemic imbalance not due to plaque rupture** ("type 2" MI): ↑ myocardial O_2 demand (eg, ↑ HR, anemia, AS) or ↑ supply (hypotension, severe anemia)
- **Direct myocardial injury:** myocarditis; Takotsubo/stress CMP; toxic CMP; cardiac contusion

Clinical manifestations (*JAMA* 2005;294:2623)

- **Typical angina:** retrosternal pressure/pain/tightness ± radiation to neck, jaw or arms precip. by exertion, relieved by rest or NTG; in ACS, new-onset, crescendo or at rest; see "Chest Pain" for likelihood ratios for different sx
- **Associated symptoms:** dyspnea, diaphoresis, N/V, palpitations or lightheadedness
- Many MIs (˜20% in older series) are initially unrecognized b/c silent or atypical sx

- Atypical sxs (incl N/V & epig pain) may be more common with inferior ischemia
- Women may have ↑ freq of atypical sx vs men

Physical exam

- Signs of ischemia: S4, new MR murmur 2° pap. muscle dysfxn, paradoxical S_2, diaphoresis
- Signs of heart failure: ↑ JVP, crackles in lung fields, ⊕ S_3, HoTN, cool extremities
- Signs of other vascular disease: asymmetric BP (aortic dissection or subclavian disease), carotid or femoral bruits, ↓ distal pulses

ECG

- ✓ w/in 10 min of presentation, q15-30min × 1 h if initial ECG non-dx, w/ any Δ in sx, and routinely at 6-12 h; compare w/ baseline
- Signs of ischemia (*JAMA* 1998;280:1256)

  STE: generally ≥1 mm in ≥2 contiguous leads (see "STEMI" for details) new or presumed new (ie, not known to be old) LBBB w/ compelling H&P

  STD ≥0.5 mm (⊕ LR 3-5), TWI ≥2 mm (⊕ LR 2-3), hyperacute Tw
- Qw or PRWP may suggest prior MI, ∴ higher pretest probability of CAD
- Dx of STEMI if old LBBB (Sgarbossa's criteria): ≥1 mm STE *concordant* w/ direction of QRS (Se 73%, Sp 92%), STD ≥1 mm V_1-V_3 (Se 25%, Sp 96%) or STE ≥5 mm *discordant* w/ QRS (Se 31%, Sp 92%)

Localization of MI

Anatomic area	ECG leads w/ STE	Coronary artery
Septal	V_1-V_2	Proximal LAD
Anterior	V_3-V_4	LAD
Apical	V_5-V_6	Distal LAD, LCx or RCA
Lateral	I, aVL	LCx
Inferior	II, III, aVF	RCA (˜85%), LCx (˜15%)
RV	V_1-V_2 & V_4R (most Se)	Proximal RCA
Posterior	ST *depression* V_1-V_3 (= STE V_7-V_9 posterior leads)	RCA or LCx

If ECG non-dx and suspicion high, consider addt'l lateral (posterior) leads (V_7-V_9) to further assess distal LCx/RCA territory. Check right-sided precordial leads in patients with IMI to help detect RV involvement

(STE in V_4R most Se). STE in III > STE in II and lack of STE in I or aVL suggest RCA rather than LCx culprit in IMI.

Cardiac biomarkers

- Troponin (Tn) preferred over CK-MB
- ✓ Tn at baseline & 3-6 h after sx onset; may also ✓ beyond 6 h if high index of suspicion based on clinical presentation or ECGs or if sx Δ
- Rise to >99th %ile in approp. clinical setting dx of MI (see "Chest Pain")
- In Pts w/ ACS & ↓ CrCl, ↓ Tn still portends poor prognosis (*NEJM* 2002;346:2047)

Other potential dx tests

- If low prob, **stress test, CT angio** or rest perfusion imaging to r/o CAD (see "Chest Pain")
- TTE (new wall motion abnl) suggestive of ACS but not specific, as may be seen if old MI
- Coronary angio gold standard for evaluation of CAD

Prinzmetal's (variant) angina

- Coronary spasm → transient STE usually w/o MI (*but* MI, AVB, VT can occur)
- Pts usually young, smokers, ± other vasospastic disorders (eg, migraines, Raynaud's)
- Most frequent between midnight and early morning when vagal tone is highest
- Provocation testing: spasm can be precipitated at angio w/ IC ergonovine or acetylchol. positive test = severe narrowing w/ sx or ECG Δs; nonobstructive CAD typically seen; rarely done as risks include refractory/recurrent spasm or arrhythmia
- Noninvasive testing: hyperventilation, 12-lead Holter, exercise study
- Treatment: often initiated empirically without provocation testing: high-dose CCB (dilt, verap or nifed all roughly ≈) & standing nitrates (+SL prn) ? α-blockers/statins; d/c smoking

  avoid high-dose ASA (can inhibit prostacyclin & worsen spasm), nonselect βB, triptans
- Cocaine-induced vasospasm: use CCB, nitrates, ASA; ? avoid βB, but data weak and labetalol appears safe (*Archives* 2010;170:874; *Circ* 2011;123:2022)

Likelihood of ACS

Feature	High (any of below)	Intermediate (no high features, any of below)	Low (no high/inter. features, may have below)
History	Chest or L arm pain like prior angina, h/o CAD (incl MI)	Chest or arm pain age >70 y, male, diabetes	Atypical sx (eg, pleuritic, sharp or positional pain)
Exam	HoTN, diaphoresis, HF,	PAD or cerebrovas-	Pain reproduced on palp.

	transient MR	cular dis.	
ECG	New STD (≥1 mm) TWI in mult leads	Old Qw, STD (0.5-0.9 mm), TWI (>1 mm)	TWF/TWI (<1 mm) in leads w/ dominant R wave
Biomarkers	⊕ Tn or CK-MB	Normal	Normal

(Adapted from ACC/AHA 2007 Guideline Update for UA/NSTEMI, *Circ* 2007;116:e148)

Approach to triage

- If hx and initial ECG & Tn non-dx, repeat ECG q15-30min × 1 h & Tn 3-6 h after sx onset
- If remain nl and low likelihood of ACS, search for alternative causes of chest pain
- If remain nl, have ruled out MI, *but* if suspicion for ACS based on hx, then still need to r/o UA w/ stress test to assess for inducible ischemia (or CTA to r/o CAD);

  if low risk (eg, age ≤70; ø prior CAD, CVD, PAD; ø rest angina) can do before d/c from ED or as outPt w/in 72 h (0% mortality, <0.5% MI, *Ann Emerg Med* 2006;47:427)

  if not low risk, admit and initiate Rx for possible ACS and consider stress test or cath

Acute Anti-Ischemic and Analgesic Treatment

Nitrates (SL or IV) 0.3-0.4 mg SL q5min ×3, then consider IV if still sx	Use for relief of sx, control HTN or Rx of HF No clear ↓ in mortality *Caution* if preload-sensitive (eg, HoTN, AS, sx RV infarct); contraindic if recent PDE5 inhibit use
β-blockers eg, metop 25-50 mg PO q6h titrate slowly to HR 50-60 IV only if HTN and no HF	↓ ischemia & progression of UA to MI (*JAMA* 1988;260:2259) STEMI: ˜20% ↓ arrhythmic death or reMI, but 30% ↑ cardiogenic shock early (espec if signs of HF), & ∴ no Δ overall mortality (*Lancet* 2005;366:1622) In Pts w/o HF, IV βB prior to 1° PCI ↓ infarct size and ↑ EF (*Circ* 2013;128:1495) *Contraindic.* PR >0.24 sec, HR <60, 2°/3° AVB, severe bron-chospasm, s/s HF or low output, risk factors for shock (eg, >70 y, HR >110, SBP <120, late presentation STEMI)
CCB (nondihydropyridines)	If cannot tolerate βB b/c bronchospasm; otherwise has similar contraindications as βB Rx
Morphine	Relieves pain, ↓ anxiety, venodilation → ↓ preload ∴ use for persistent sx or CHF. Do not mask refractory sx. May delay onset of antiplatelet Rx (*JACC* 2014;63:630)
Oxygen	Use prn for resp distress or to keep S_aO_2 >90% ? ↑ infarct size in STEMI w/o hypoxia (*Circ* 2015;131:2143)

Other early adjunctive therapy

- **High-intensity statin therapy** (eg, atorvastatin 80 mg qd) ↓ ischemic events w/ benefit emerging w/in wks (*JAMA* 2001;285:1711 & *JACC* 2005;46:1405) ↓ peri-PCI MI (*JACC* 2010;56:1099); ↓ contrast-induced nephropathy (*JACC* 2014;63:71)
- **ACEI/ARB:** start once hemodynamics and renal function stable Strong indication for ACEI if heart failure, EF <40%, HTN, DM, CKD; ˜10% ↑ mortality, greatest benefit in ant. STEMI or prior MI (*Lancet* 1994;343:1115 & 1995;345:669)

  Start w/ low dose of short-acting (eg, captopril 6.25 mg tid), titrate up as tolerated ARB appear ≈ ACEI (*NEJM* 2003;349:20); give if contraindic to ACEI
- Ezetimibe, aldosterone blockade, and ranolazine discussed later (long-term Rx)
- IABP: can be used for refractory angina when PCI not available

NSTE-ACS (*Circ* 2014;130:e344)

Key issues are antithrombotic regimen and invasive vs conservative strategy

Antiplatelet Therapy

Aspirin 162-325 mg × 1, then 81 mg qd (non-enteric coated, chewable)	50-70% ↓ D/MI (*NEJM* 1988;319:1105) Low dose (˜81 mg) pref long term (*NEJM* 2010;363:930) If allergy, use clopi and/or desensitize to ASA

$P2Y_{12}$ (ADP receptor) inhibitor (choose one of the following in addition to ASA). Timing remains controversial. Some data support benefit of clopidogrel preRx prior to angiography (*JAMA* 2012;308:2507). Ticagrelor was given upstream in pivotal study. Prasugrel should be given once PCI planned (ie, anatomy defined). European guidelines recommend $P2Y_{12}$ inhibitor as soon as possible after presentation (*EHJ* 2011;32:2999).

• **Ticagrelor** 180 mg × 1 → 90 mg bid Reversible binding, but wait 3-5 d prior to surg Use only with ASA <100 mg qd	Preferred over clopidogrel More rapid and potent plt inhib c/w clopi 16% ↓ CVD/MI/stroke & 21% ↓ CV death c/w clopi; ↑ non-CABG bleeding (*NEJM* 2009;361;1045) Sensation of dyspnea (S_aO_2 & PFTs nl) and ventricular pauses; perhaps b/c blocks adenosine reuptake
• **Prasugrel** 60 mg × 1 at PCI → 10 mg qd (consider 5 mg/d if <60 kg) Wait 7 d prior to surgery	Use at time of PCI; preferred over clopidogrel More rapid and potent plt inhib c/w clopi 19% ↓ CVD/MI/stroke in ACS w/ planned PCI vs clopi, but ↑ bleeding (*NEJM* 2007;359:2001), incl fatal bleeds Not sup to clopi if med mgmt w/o PCI (*NEJM* 2012;367:1297) In NSTE-ACS, should be given at time of PCI and not upstream due to ↑ bleeding (*NEJM* 2013;369:999) Contraindic. if h/o TIA/CVA; ? avoid if >75 y

• **Clopidogrel**[*] 300-600 mg × 1 → 75 mg qd Requires ˜6 h to steady state	ASA+clopi → 20% ↓ CVD/MI/stroke vs ASA alone ↑ benefit if given hrs *prior* to PCI, but then if require CABG, need to wait >5 d after d/c clopi
• **Cangrelor** Only IV $P2Y_{12}$ inhibitor Rapid onset/offset; t½ 3-5 min	22% ↓ CV events (mostly peri-PCI MI and stent thrombosis) vs clopi 300 mg at time of PCI; no significant ↑ bleeding (*NEJM* 2013;368:1303) Unclear benefit if upstream clopi (*NEJM* 2009;361:2318) and no data vs prasugrel or ticagrelor
GP IIb/IIIa inhibitors (GPI) Abciximab: LD 0.25 mg/kg IV, then 0.125 mcg/kg/min Eptifibatide: LD 180 mcg/kg IV ×2, then 2 mcg/kg/min (½ dose if CrCl <50 mL/min) Tirofiban: LD 25 mcg/kg IV, then 0.15 mcg/kg/min (½ dose if CrCl <30 mL/min)	No clear benefit for routinely starting prior to PCI and ↑ bleeding (*NEJM* 2009;360:2176). Consider epti or tiro if refractory ischemia despite optimal Rx while awaiting angio. Consider in high-risk Pts (eg, large thrombus burden) at time of PCI, espec if using clopi and not preRx'd. Often administered 18-24 h post PCI, but shorter duration (˜2 h) may be as efficacious and with ↓ bleeding (*JACC* 2009;53:837); D/C eptifibatide/tirofiban ≥2-4 h and abciximab ≥12 h prior to urgent CABG.

[*]Utility of platelet function testing remains unproven (*JAMA* 2011;305:1097; *NEJM* 2012;367:2100), but studies underpowered. ˜30% pop has ↓ fxn *CYP2C*19 allele → ↑ CV events if PCI on clopi compared w/ wild type (*NEJM* 2009;360:354; *JAMA* 2010;304:1821).

Anticoagulant Therapy (choose one)

UFH: 60 U/kg IVB (max 4000 U) then 12 U/kg/h (max 1000 U/h initially) × 48 h or until end of PCI	24% ↓ D/MI (*JAMA* 1996;276:811) Titrate to aPTT 1.5-2× control (˜50-70 sec) Hold until INR <2 if already on warfarin
Enoxaparin (low-molec-wt heparin) 1 mg/kg SC bid (± 30 mg IVB) (qd if CrCl <30) × 2-8 d or until PCI	˜10% ↓ D/MI vs UFH (*JAMA* 2004;292:45,89). Can perform PCI on enox (*Circ* 2001;103:658), but ↑ bleeding if switch b/w enox and UFH.
Bivalirudin (direct thrombin inhibitor) 0.75 mg/kg IVB at PCI → 1.75 mg/kg/h	↓ bleeding (espec vs UFH + GPI), ± ↑ early MI (*Lancet* 2014;384:599). Use instead of UFH if HIT.
Fondaparinux (Xa inhibitor) 2.5 mg SC qd × 2-8 d	C/w enox, 17% ↓ death & 38% ↓ bleeding (*NEJM* 2006;354:1464). However, ↑ risk of catheter thrombosis; ∴ must supplement w/ UFH if PCI.

Coronary angiography (*Circ* 2014;130:e344)

- **Immediate/urgent coronary angiography** (w/in 2 h) if refractory/recurrent angina or hemodynamic or

electrical instability

- **Invasive (INV) strategy =** routine angiography w/in 72 h (*NEJM* 2009;360:2165)

  Early (w/in 24 h) if: ⊕ Tn, ST Δ, GRACE risk score (www.outcomes-umassmed.org/grace) >140

  Delayed (ie, acceptable anytime w/in 72 h) if no indication for early/immediate cath but has other high-risk predictors incl: diabetes, EF <40%, GFR <60, post-MI angina , TIMI Risk Score ≥3, GRACE score 109-140, PCI w/in 6 mo, prior CABG

  Invasive strategy leads to 32% ↓ rehosp for ACS, nonsignif 16% ↓ MI, no Δ in mortality c/w cons. (*JAMA* 2008;300:71); ↑ peri-PCI MI counterbalanced by ↓ ↓ in spont. MI; mortality benefit seen in some studies, likely only if cons. strategy w/ low rate of angio

  ↑ risk of death or MI if invasive strategy deferred beyond 72 h (*JAMA* 2003;290:1593)

- **Conservative (CONS) strategy =** selective angio. Medical Rx with pre-d/c stress test; angio only if recurrent ischemia or ⊕ ETT. *Indicated for:* low TIMI Risk Score, Pt or physician preference in absence of high-risk features, low-risk women (*JAMA* 2008;300:71).

TIMI Risk Score (TRS) for UA/NSTEMI (*JAMA* 2000;284:835)

Calculation of Risk Score		Application of Risk Score	
Characteristic	**Point**	**Score**	**D/MI/UR by 14 d**
Historical		0-1	5%
Age ≥65 y	1	2	8%
≥3 Risk factors for CAD	1	3	13%
Known CAD (stenosis ≥50%)	1	4	20%
ASA use in past 7 d	1	5	26%
Presentation		6-7	41%
Severe angina (≥2 episodes w/in 24 h)	1	Higher risk Pts (TRS ≥3) derive ↑ benefit from LMWH, GP IIb/IIIa inhibitors and early angiography (*JACC* 2003;41:89S)	
ST deviation ≥0.5 mm	1		
⊕ cardiac marker (troponin, CK-MB)	1		

RISK SCORE = Total points **(0-7)**

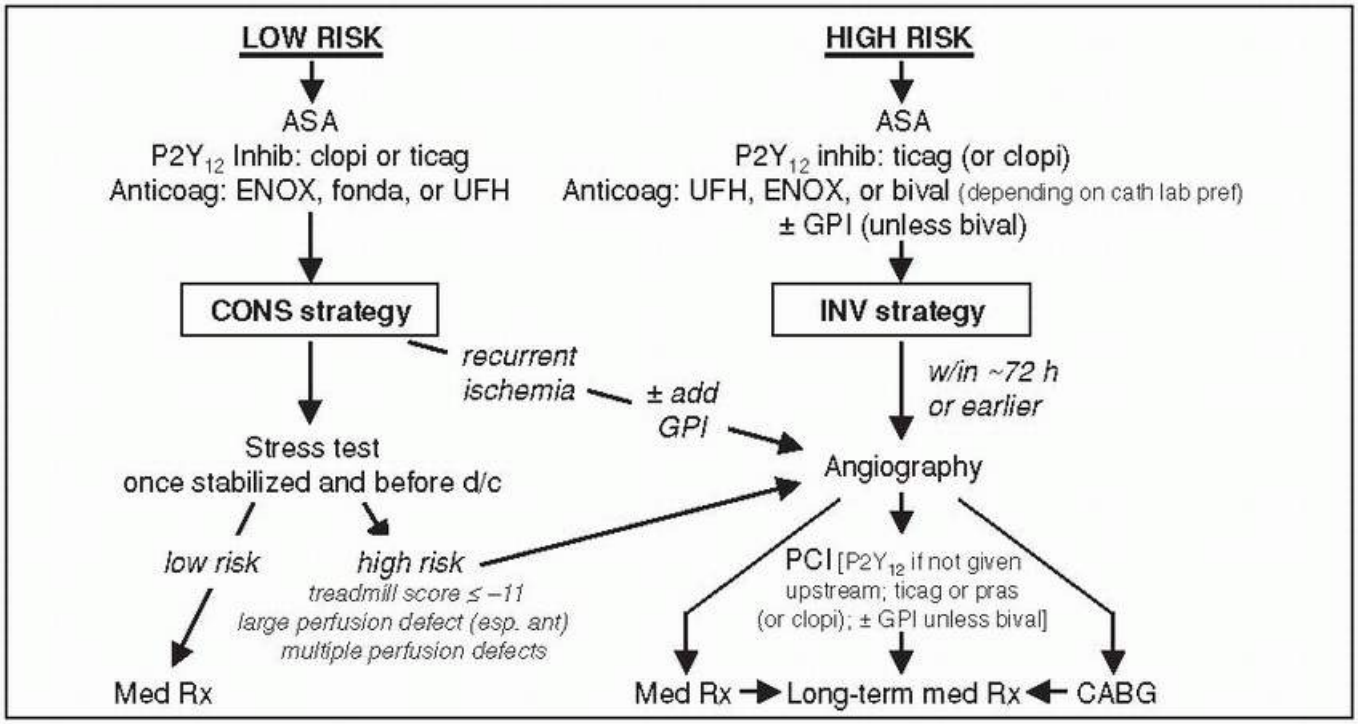

Figure 1-2 Approach to UA/NSTEMI

STEMI

Requisite STE (at J point)

- ≥2 contiguous leads w/ ≥1 mm (except for V_2-V_3: ≥2 mm in ♂ and ≥1.5 mm in ♀), or
- New or presumed new LBBB w/ compelling H&P, or
- True posterior MI: ST depression V_1-V_3 ± tall Rw w/ STE on posterior leads (V_7-V_9)

Reperfusion ("time is muscle")

- Immediate reperfusion (ie, opening occluded culprit coronary artery) is critical
- In PCI-capable hospital, goal should be **primary PCI w/in 90 min** of 1st medical contact
- In non-PCI-capable hospital, consider *transfer* to PCI-capable hospital (see below), o/w **fibrinolytic therapy** w/in 30 min of hospital presentation. If dx confirmed, administration of fibrinolytic in ambulance prior to arrival can be considered
- Do not let decision regarding *method* of reperfusion delay *time* to reperfusion

Primary PCI (*NEJM* 2007;356:47; *JACC* 2013;61:e78)

- Definition: immediate PCI upon arrival to hospital or transfer for immediate PCI
- Indications: STE + sx onset < 12 h; ongoing ischemia 12-24 h after sx onset; shock or severe HF regardless of time
- Superior to lysis: 27% ↓ death, 65% ↓ reMI, 54% ↓ stroke, 95% ↑ ICH (*Lancet* 2003;361:13)

- *Transfer* to center for 1° PCI superior to lysis (*NEJM* 2003;349:733). ∴ If initially seen at non-PCI capable hosp, transfer for PCI if door-in to door-out time can be ≤30 min and 1st medical contact to PCI time estimated to be ≤120 min.
- Thrombus aspiration: small study showed ↓ mortality, but larger studies show no benefit and ↑ stroke (*Lancet* 2008;371:1915; *NEJM* 2013;369:1587 & 2015;372:1389)
- Small studies have demonstrated ↓ MACE w/ complete revasc vs culprit artery alone (*NEJM* 2013; 369:1115; *JACC* 2015;65:963), large study ongoing; alternatively, could assess ischemia due to residual lesions w/ imaging stress (*Circ* 2011;124:e574)

Fibrinolysis vs Hospital Transfer for Primary PCI: Assess Time and Risk

1. **Time required for transport to skilled PCI lab:** door-to-balloon <120 min & [door-to-balloon]-[door-to-needle] <1 h favors transfer for PCI
2. **Risk from STEMI:** high-risk Pts (eg, shock) fare better with mechanical reperfusion
3. **Time to presentation:** efficacy of lytics ↓ w/ ↑ time from sx onset, espec >3 h
4. **Risk of fibrinolysis:** if high risk of ICH or bleeding, PCI safer option Adapted from ACC/AHA 2013 STEMI Guidelines (*Circ* 2013;127:529)

Fibrinolysis

- Indic: STE/LBBB + sx <12 h + >120 min before PCI can be performed; benefit if sx >12 h less clear; reasonable if persist. sx & STE or hemodyn instability or large territory at risk
- Fibrin-spec lytics (TNK, TPA, RPA) ↑ artery patency vs streptokinase (*JACC* 2013;61:e78)
- Mortality ↓ ~20% in anterior MI or LBBB and ~10% in IMI c/w ø reperfusion Rx
- Prehospital lysis (ie, ambulance): further 17% ↓ in mortality (*JAMA* 2000;283:2686)
- ~1% risk of ICH; high-risk groups include elderly (~2% if >75 y), women, low wt
- Although age not contraindic., ↑ risk of ICH in elderly (>75 y) makes PCI more attractive
- Successful reperfusion gauged by sx & ECG: sudden CP resolution & ≥70% resolution of STE indicative of successful reperfusion; conversely, STE resolution <50% after 60-90 min should prompt consideration of rescue PCI (qv)

Contraindications to Fibrinolysis

Absolute contraindications	Relative contraindications
• Any prior ICH • Intracranial neoplasm, aneurysm, AVM	• Hx of severe HTN or SBP >180 or DBP >110 on presentation (? absolute contra. if low-risk MI)

- Ischemic stroke w/in 3 mo (unless acute w/in 4.5 h) or closed head trauma w/in 3 mo
- Active internal bleeding or known bleeding diathesis
- Head/facial trauma w/in 3 mo
- Head/spinal surgery w/in 2 mo
- Suspected aortic dissection
- Severe uncontrollable HTN
- For SK, SK Rx w/in 6 mo
- Ischemic stroke >3 mo prior
- Dementia
- Recent traumatic or prolonged CPR >10 min
- Trauma or major surgery w/in 3 wk
- Recent internal bleed (w/in 2-4 wk); active PUD
- Noncompressible vascular punctures
- Prior SK exposure (if considering SK)
- Pregnancy
- Current use of anticoagulants

Nonprimary PCI

- Facilitated or pharmacoinvasive PCI = upstream lytic, GPI or GPI + ½ dose lytic before PCI; in general no clear clinical benefit & ↑ bleeding (*Lancet* 2006;367:569; *NEJM* 2013;368:1379)
- Rescue PCI if shock, unstable, failed reperfusion or persistent sx (*NEJM* 2005;353:2758)
- Routine angio ± PCI w/in 24 h of successful lysis: ↓ D/MI/revasc (*Lancet* 2004;364:1045) and w/in 6 h ↓ reMI, recurrent ischemia, & HF compared to w/in 2 wk (*NEJM* 2009;360:2705);

  ∴ *if lysed at non-PCI capable hospital, consider transfer to PCI-capable hospital ASAP espec if high-risk presentation (eg, anterior MI, inferior MI w/ low EF or RV infarct, extensive STE or LBBB, HF, ↓ BP or ↑ HR)*
- *Late* PCI (median day 8) of occluded infarct-related artery: no benefit (*NEJM* 2006;355:2395)

Antiplatelet Therapy

Aspirin 162-325 mg × 1 (crushed/chewed) then 81 mg qd	23% ↓ in death (*Lancet* 1988;ii:349) Should not be stopped if CABG required
P2Y$_{12}$ inhibitor Give ASAP (do not wait for angio) Ticagrelor or prasugrel (if PCI) as detailed above Clopidogrel: 600 mg pre-PCI; 300 mg if lysis (no LD if >75 y) → 75 mg qd	*Lysis:* clopidogrel 41% ↑ in patency, 7% ↓ mort, no Δ major bleed or ICH (*NEJM* 2005;352:1179; *Lancet* 2005;366:1607); no data for pras or ticag w/ lytic *PCI:* prasugrel and ticagrelor ↓ CV events c/w clopi (*Lancet* 2009;373:723 & *Circ* 2010;122:2131) *Nb, antiplt effects delayed in STEMI Pts*
GP IIb/IIIa inhibitors abciximab, eptifibatide, tirofiban	*Lysis:* no indication (*Lancet* 2001;357:1905) *Peri-PCI:* 60% ↓ D/MI/UR (*NEJM* 2001;344:1895)

Adapted from ACC/AHA 2013 STEMI Guidelines Update (*Circ* 2013;127:529); *Lancet* 2013;382:633

Anticoagulant Therapy (choose one)

UFH 60 U/kg IVB (max 4000	No demonstrated mortality benefit ↑ patency with fibrin-specific lytics

U) 12 U/kg/h (max 1000 U/h initially)	Titrate to aPTT 1.5-2× control (˜50-70 sec)
Enoxaparin *Lysis:* 30 mg IVB → 1 mg/kg SC bid (adjust for age >75 & CrCl) *PCI:* 0.5 mg/kg IVB	*Lysis:* 17% ↓ D/MI w/ ENOX × 7 d vs UFH × 2 d (*NEJM* 2006;354;1477) *PCI:* ↓ D/MI/revasc and ≈ bleeding vs UFH (*Lancet* 2011;378:693)
Bivalirudin 0.75 mg/kg IVB → 1.75 mg/kg/hr IV (ongoing research on prolonged infusions)	*PCI:* ↓ bleeding (espec vs UFH + GP IIb/IIIa inhib), ± ↑ MI, ↑ stent thromb (not mitigated by longer infusion), ↓ mortality in some but not all trials (*Lancet* 2014;384:599; *JAMA* 2015;313:1336; MATRIX NEJM 2015)
Fondaparinux 2.5 mg IVB → 2.5 mg SC qd Contraindic if CrCl ≤30 mL/min	*Lysis:* superior to placebo & to UFH, with less bleeding (*JAMA* 2006;295;1519) *PCI:* risk of catheter thromb.; should not be used

Adapted from ACC/AHA 2013 STEMI Guidelines (*Circ* 2013;127:529); *Lancet* 2013;382:633

Intraaortic Balloon Pump (IABP) Counterpulsation

- Inflates during diastole and deflates during systole to ↑ coronary flow and ↑ afterload
- *Routine* use in high-risk STEMI → ↑ stroke/bleeds w/o Δ in survival, infarct size or EF (*EHJ* 2009;30:459; *JAMA* 2011;306:1329)
- In cardiogenic shock, no survival benefit w/ IABP if early revasc (*NEJM* 2012;367:1287); 18% ↓ death in Pts w/ cardiogenic shock treated with lytic (*EHJ* 2009;30:459)

LV failure (˜25%)

- Diurese to achieve PCWP 15-20 → ↑ pulmonary edema, ↓ myocardial O_2 demand
- ↓ Afterload → ↑ stroke volume & CO, ↓ myocardial O_2 demand can use IV NTG or nitroprusside (risk of coronary steal) → short-acting ACEI
- Inotropes if HF despite diuresis & ↓ afterload; use dopamine, dobutamine or milrinone
- **Cardiogenic shock** (˜7%) = MAP < 60 mmHg, CI <2 L/min/m^2, PCWP >18 mmHg; inotropes, mech support [eg, VAD, IABP (see above)] to keep CI >2; pressors to keep MAP >60; if not done already, coronary revasc (*NEJM* 1999;341:625)

IMI complications (*Circ* 1990;81:401; *NEJM* 1994;330:1211; *JACC* 2003;41:1273)

- **Heart block** (˜20%, occurs because RCA typically supplies AV node) 40% on present., 20% w/in 24 h, rest by 72 h; high-grade AVB can develop abruptly Rx: atropine, epi, aminophylline (100 mg/min × 2.5 min), temp pacing wire
- **RV infarct** (proximal RCA occlusion → compromised flow to RV marginal branch) Angiographically in 30-50%, but only ½ of those clinically signif. HoTN; ↑ JVP, ⊕ Kussmaul's; 1 mm STE in V_4R; RA/PCWP ≥0.8;

RV dysfxn on TTE

Rx: optimize preload (RA goal 10-14, *BHJ* 1990;63:98); ↑ contractility (dobutamine); maintain AV synchrony (pacing as necessary); reperfusion (*NEJM* 1998;338:933); mechanical support (IABP or RVAD); pulmonary vasodilators (eg, inhaled NO)

Mechanical complications (incid. <1% for each; typically occur a few days post-MI)

- **Free wall rupture:** ↑ risk w/ lysis, large MI, ↑ age, ♀, HTN; p/w PEA or hypoTN, pericardial sx, tamponade; Rx: volume resusc., ? pericardiocentesis, inotropes, **surgery**
- **VSD:** large MI in elderly; AMI → apical VSD, IMI → basal septum; 90% w/ harsh murmur ± thrill (*NEJM* 2002;347:1426); Rx: diuretics, vasodil., inotropes, IABP, **surgery,** perc. closure
- **Papillary muscle rupture:** more common after inf MI (PM pap. muscle supplied by PDA alone) than ant MI (AL pap. muscle supplied by diags & OMs); 50% w/ new murmur, rarely a thrill, → *v* wave in PCWP tracing; asymmetric pulmonary edema on CXR (often worse in RUL due to direction of jet). Rx: diuretics, vasodilators, IABP, **surgery.**

Arrhythmias post-MI

- Treat as per ACLS for unstable or symptomatic bradycardias & tachycardias
- **AF** (10-16% incidence): βB or amio, ± digoxin (particularly if HF), heparin
- **VT/VF:** lido or amio × 6-24 h, then reassess; ↑ βB as tol., replete K & Mg, r/o ischemia; early monomorphic (<48 h post-MI) does *not* carry bad prognosis. Beyond 48 h, VT/VF a/w worse prognosis → consider wearable defibrillator (qv).
- Accelerated idioventricular rhythm (AIVR): slow VT (<100 bpm), often seen after successful reperfusion; typically self-terminates and does not require treatment
- May consider ***backup* transcutaneous pacing** (TP) if: 2° AVB type I, BBB
- **Backup TP *or* initiate transvenous pacing** if: 2° AVB type II; BBB + AVB
- **Transvenous pacing** (TV) if: 3° AVB; new BBB + 2° AVB type II; alternating LBBB/RBBB (can bridge w/ TP until TV, which is best accomplished under fluoroscopic guidance)

Other Post-MI Complications

Complication	Clinical features	Treatment
LV thrombus	~30% incid. (espec lg antero-apical MI)	Anticoagulate × 3-6 mo
Ventricular aneurysm	Noncontractile outpouching of LV; 8-15% incid. (espec ant); persist STE	Surgery or perc repair if HF, thromboemboli, arrhythmia

Ventricular pseudoaneurysm	Rupture → sealed by thrombus and pericardium (espec in inf). Typically w/ narrow neck as c/w true aneurysm; Dx w/ cardiac MRI, CTA, or TEE.	Urgent surgery (or percutaneous repair)
Pericarditis	10-20% incid.; 1-4 d post-MI ⊕ pericardial rub; ECG Δs rare	High-dose ASA > aceta., colchicine, narcotics; minimize anticoag
Dressler's syndrome	<4% incid.; 2-10 wk post-MI fever, pericarditis, pleuritis	High-dose aspirin, NSAIDs

Prognosis

- In registries, in-hospital mortality is 6% w/ reperfusion Rx (lytic or PCI) and ~20% w/o
- Predictors of mortality: age, time to Rx, anterior MI or LBBB, heart failure (*Circ* 2000;102:2031)

Killip Class

Class	Definition	Mort.
I	no CHF	6%
II	⊕ S3 and/or basilar rales	17%
III	pulmonary edema	30-40%
IV	cardiogenic shock	60-80%

(*Am J Cardiol* 1967;20:457)

Forrester Class Mortality

		PCWP (mmHg)	
		<18	>18
CI	>2.2	3%	9%
	≤2.2	23%	51%

(*NEJM* 1976;295:1356)

TIMI Risk Score for STEMI

Characteristic	Points	Characteristic (cont)	Points	Score	30-d death
Age 65-74/≥75 y	2/3	Ant MI or new LBBB	1	0-2	˜1-2%
SBP <100 mmHg	3	h/o DM, HTN or angina	1	3-4	˜4-6%
HR >100 bpm	2	Wt <67 kg	1	5-6	˜10-15%
Killip class II-IV	2	Time to Rx >4 h	1	≥7	≥20%

(*JAMA* 2001;286:1356)

PREDISCHARGE CHECKLIST AND LONG-TERM POST-ACS MANAGEMENT

Risk stratification

- Stress test if anatomy undefined; consider stress if signif residual CAD post-PCI of culprit
- Assess LVEF prior to d/c; EF ↑ ˜6% in STEMI over 6 mo (*JACC* 2007;50:149)

Medications (barring contraindications)

- **Aspirin:** 81 mg daily
- **$P2Y_{12}$ inhib** (ticagrelor or prasugrel preferred over clopi): treat for *at least* 12 mo Prolonged Rx beyond 12 mo → ↓ CV death, MI, & stroke (& stent thrombosis) w/ ↑ in bleeding, but no ↑ fatal bleeding or ICH. For Rx beyond 1st 12 mo, comparable efficacy w/ ticagrelor 90 or 60 mg bid, better safety & tolerability with 60 bid (*NEJM* 2015;372:1791; *JACC* 2007;49:1982 & 2015;65:2211).

  Some PPIs interfere w/ biotransformation of clopi and ∴ plt inhibition, but no convincing impact on clinical outcomes (*Lancet* 2009;374:989; *NEJM* 2010;363:1909); use w/PPIs if h/o GIB or multiple GIB risk factors (*JACC* 2010;56:2051)
- **β-blocker:** 23% ↓ mortality after MI
- **Statin:** high-intensity lipid-lowering (eg, atorvastatin 80 mg, *NEJM* 2004;350:1495)
- **Ezetimibe:** ↓ CV events including MI and ischemic stroke when added to statin (IMPROVE-IT, *NEJM* 2015;372:1500)
- **ACEI:** lifelong if HF, ↓ EF, HTN, DM; 4-6 wk or at least until hosp. d/c in all STEMI ? long-term benefit in CAD w/o HF (*NEJM* 2000;342:145 & 2004;351:2058; *Lancet* 2003;362:782)
- **Aldosterone antag:** 15% ↓ mortality if EF <40% & either s/s of HF or DM; contraindic if renal dysfxn (Cr >2.5 in men, >2 in women) or K >5 (*NEJM* 2003;348:1309)

- Nitrates: standing if symptomatic; SL NTG prn for all
- Ranolazine: inhibits late inward Na current, prevents intracellular Ca overload; ↓ recurrent ischemia (*JAMA* 2007;297:1775)
- Oral anticoagulants: if warfarin needed in addition to ASA/clopi (eg, AF or LV throm-bus), target INR 2-2.5. ? stop ASA if at high bleeding risk on triple Rx (*Lancet* 2013;381:1107). Not FDA approved: low-dose rivaroxaban (2.5 mg bid) in addition to ASA & clopi → 16% ↓ D/MI/stroke and 32% ↓ all-cause death, but ↑ major bleeding and ICH (*NEJM* 2012;366:9).
- NSAIDs/COX2 inhib relatively contraindic b/c ? ↑ death, MI, HF, rupture (*Circ* 2006;113:2906)

ICD (*NEJM* 2008;359:2245)

- If sust. VT/VF >2 d post-MI not due to reversible ischemia; consider wearable defibril-lator or ICD (*JACC* 2014;130:94)
- Indicated in 1° prevention of SCD if post-MI w/ EF ≤30-40% (NYHA II-III) or ≤30-35% (NYHA I); need to wait ≥40 d after MI (*NEJM* 2004;351:2481 & 2009;361:1427)

Risk factors and lifestyle modifications (*Circ* 2014;129(Suppl 2):S1 & S76)

- Low chol. (<200 mg/d) & fat (<7% saturated) diet; ? Ω-3 FA
- Traditional LDL-C goal <70 mg/dL; new recs w/o LDL-C target, rather simply high-intensity statin; may change w/ IMPROVE-IT trial showing that lower is better (lower CV event rate in arm with achieved LDL-C of 54 vs 70 mg/dL)
- BP <140/90 and consider <130/80 mmHg (HTN 2015;65:1372); smoking cessation
- If diabetic, tailor HbA1c goal based on Pt (avoid TZDs if HF)
- Exercise (30-60 min 5-7×/wk); cardiac rehab; BMI goal 18.5-24.9 kg/m^2
- Influenza & pneumococcal vaccination (*Circ* 2006;114:1549; *JAMA* 2013;310:1711); screen for depression

CARDIAC RISK ASSESSMENT FOR NONCARDIAC SURGERY

Goal: characterize risk of Pt & procedure → appropriate testing (ie, results will Δ management) and interventions (ie, reasonable probability of → risk of MACE)

Preoperative assessment

- Clinical assessment: evidence of active cardiac disease and/or risk factors
- Functional capacity (METs)
- Surgery-specific risk

Clinical Assessment

Active cardiac conditions	Clinical risk factors
• MI w/in 30 d or current unstable or severe angina	• h/o ischemic heart

- Decompensated HF
- Significant arrhythmia (eg, Mobitz II, high-grade AVB, 3° AVB, new or sx VT, SVT w/ HR >100, sx brady)
- Severe AS or sx MS

disease
- h/o congestive HF
- h/o stroke or TIA
- Diabetes on insulin
- Renal insuffic. (Cr >2 mg/dL)

Functional Capacity

1-4 METs (poor)	4-10 METs (moderate-to-good)	>10 METs (excellent)
• ADLs • Walk indoors • Walk 1-2 level blocks	• Climb a flight of stairs/hill • Walk briskly; heavy housework • Golf, doubles tennis	• Strenuous sports

Surgery-Specific Risk

High (>5% risk)	Intermediate (1-5%)	Low (<1%)
• Aortic or other major vascular • Peripheral vasc.	• Intrathoracic; intraperitoneal; prostate & major urologic • CEA; head & neck • Orthopedic	• Endoscopic • Breast; superficial • Cataract; ambulatory • Dental

Noninvasive Testing Result

High risk	Intermediate risk	Low risk
Ischemia at <4 METs *manifested* by ≥1 of: • Horiz/down ST ↓ ≥*1* mm or STE • ≥5 abnl leads or ischemic ECG Δs lasting >3 min after exertion • SBP ↓ 10 mmHg or typical angina	***Ischemia at* 4-6 *METs*** *manifested by ≥ 1 of:* • Horiz/down ST ↓ ≥1 mm • 3-4 abnl leads • 1-3 min after exertion	***No ischemia or at* >7 METs w/** • ST ↑ ≥1 mm or • 1-2 abnl leads

Imaging with excellent NPV, poor PPV. Consider if high-risk patient.

- **Revised Cardiac Risk Index** (RCRI): 6 risk factors = 5 clinical risk factors above and type of surgery

(intrathoracic, intra-abd, or suprainguinal vascular) (*Circ* 1999;100:1043) # of risk factors predicts risk of MACE: ≤1 RF → <1%, 2 RFs → 6.6%, ≥3 RFs → 11%

- Comorbidity indices (eg, Charlson index) may predict mortality (*Am J Med Qual* 2011;26:461)

Preoperative testing (*Circ* 2014;130:e278)

- ECG if known cardiac disease and possibly reasonable in all, except if low-risk surgery
- TTE if any of the following and prior TTE > 12 mo ago or prior to Δ in sx:

  dyspnea of unknown origin

  hx of HF w/ ↑ dyspnea

  suspected valvular disease (eg, murmur on exam)

  ≥moderate stenosis/regurg
- Stress test (usually pharmacologic) if:

  active cardiac issues where stress testing is indicated (qv), or not low-risk surgery, RCRI ≥2, poor or unknown fxnal capacity, and results *will Δ mgmt* (ie, modify or delay surgery, undergo coronary revascularization, etc.) overall low PPV to predict periop CV events
- Angiography: based on noninvasive stress results for standard indications, although systematic angio ↓ 2-5 y mortality in Pts undergoing vascular surgery (*JACC* 2009;54:989)
- ? consider CXR & ECG in preop evaluation of severely obese Pts (*Circ* 2009;120:86)

Coronary artery disease

- If possible, wait ˜60 d after MI in the absence of revascularization before elective surgery
- After PCI: delay elective surgery 14 d after balloon angioplasty, 30 d after BMS implantation, and ideally 6 mo after DES implantation

- Coronary revascularization should be based on standard indications (eg, ACS, refractory sx, lg territory at risk). Has not been shown to Δ risk of death or postop MI when done prior to elective vasc. surgery based on perceived cardiac risk (*NEJM* 2004;351:2795) or documented extensive ischemia (*AJC* 2009;103:897).

Heart failure

- Decompensated HF should be optimally treated prior to elective surgery
- ↓ EF (<30%) associated with poor outcomes
- 30-d CV event rate: symptomatic HF > asx HFrEF > asx HFpEF > no HF

Valvular heart disease

- If meet criteria for valve intervention (qv), do so before elective surgery (postpone if necessary)
- If severe valve disease and surgery urgent, intra- & postoperative hemodynamic monitoring reasonable (espec for AS, since at ↑ risk even if sx not severe; be careful to maintain preload, avoid hypotension, and watch for atrial fibrillation)
- If severe AS and Pt not eligible for or impractical to do AVR prior to noncardiac surgery, balloon aortic valvuloplasty (BAV) and transcatheter aortic valve replacement (TAVR) can be considered but not routinely

recommended (*Circ* 2008;118:e523)

Cardiac implantable electronic devices (CIEDs)

- Includes PPM, CRT, ICD
- Should be discussion between surgical team & CIED team regarding: need for device (eg, complete heart block) & consequences if interference w/ fxn likelihood of electromagnetic interference consideration of reprogramming, magnet use, etc.

Pre- & perioperative pharmacologic management

- **ASA:** continue in Pts w/ existing indication. Initiation just prior to surgery does not ↓ 30-d ischemic events and ↑ bleeding (*NEJM* 2014;370:1494), but Pts w/ recent stents excluded.
- **Dual antiplatelet therapy** in Pts undergoing urgent surgery: continue 4-6 wk after PCI (BMS or DES) unless risk of bleeding > benefit of prevention of stent thrombosis. If must discontinue ADP receptor blocker, continue ASA and restart ADP receptor blocker ASAP.
- **β-blockers** (*Circ* 2009;120:2123; *JAMA* 2010;303:551; *Am J Med* 2012;125:953) Continue βB in Pts on them chronically. Do not discontinue βB abruptly postop, as may cause sympathetic activation from withdrawal. Use IV agents peri-operatively if Pt unable to take PO.

  In terms of initiating βB, conflicting evidence; may depend on how administered. Some studies show ↓ death & MI (*NEJM* 1996;335:1713 & 1999;341:1789), another showed ↓ MI, but ↑ death & stroke and ↑ bradycardia/HoTN (*Lancet* 2008;371;1839).

  ? consider initiating if intermed- or high-risk ⊕ stress test, or RCRI ≥3, espec if vasc surgery

  Ideally initiate at least 1 wk prior to surgery, use low-dose, short-acting βB, and titrate slowly and carefully to achieve desired individual HR and BP goal (? HR ~55-65). Avoid bradycardia and HoTN.
- **Statins:** ↓ ischemia & CV events in Pts undergoing vascular surg (*NEJM* 2009;361:980); may reduce AF, MI, LOS in statin-naïve Pts (*Arch Surg* 2012;147:181). Consider in Pts w/ a clinical risk factor undergoing non-low-risk surgery.
- ACEI/ARB: may cause HoTN perioperatively. If held before surgery, restart ASAP.
- Amiodarone: ↓ incidence of postop AF

  oral (eg, 600 mg qd × 7 d preop, then 200 mg qd until discharge) & IV regimens equivalent but effective only if initiated ≥1 d prior to surgery (*Pacing Clin Electrophysiol* 2013;36:1017)

  cardiac surgery: ↓ postop AF, length of stay & cost (*NEJM* 1997;337:1785) thoracic surgery: ↓ postop AF but *not* length of stay or cost (*J Thorac* CV *Surg* 2010;140:45; *Ann Thorac Surg* 2012;94:339; *Eur J Cardiothorac Surg* 2014;45:120). Not advised if severe lung disease or undergoing pneumonectomy (*Ann Thorac Surg* 2011;92:1144).

Postoperative monitoring

- ✓ Postop ECG if known CAD or high-risk surgery. Consider if >1 risk factor for CAD.
- ✓ Postop troponin only if new ECG Δs or chest pain suggestive of ACS. Elevated Tn postop predicts mortality, but may simply be a marker for underlying CAD (*Annals* 2011;154:523; *JAMA* 2012;307:2295). Routine ✓ postop in all Pts (even just high-risk Pts) has not been proven to modify outcomes and it is not routinely recommended.

Myocardial, Valvular, and Pericardial Disease

HEART FAILURE

Definitions (*Braunwald's Heart Disease*, 10th ed., 2014)

- Failure of heart to pump blood forward at sufficient rate to meet metabolic demands of peripheral tissues, or ability to do so only at abnormally high cardiac filling pressures
- Low output (↓ cardiac output) vs high output (↑ stroke volume ± ↑ cardiac output)
- Left-sided (pulmonary edema) vs right-sided (↑ JVP, hepatomegaly, peripheral edema)
- Backward (↑ filling pressures, congestion) vs forward (impaired systemic perfusion)
- Systolic (inability to expel sufficient blood) vs diastolic (failure to relax and fill normally)
- Reduced (HFrEF) vs preserved (HFpEF) left ventricular ejection fraction
- Some degree of systolic and diastolic dysfxn may occur regardless of ejection fraction

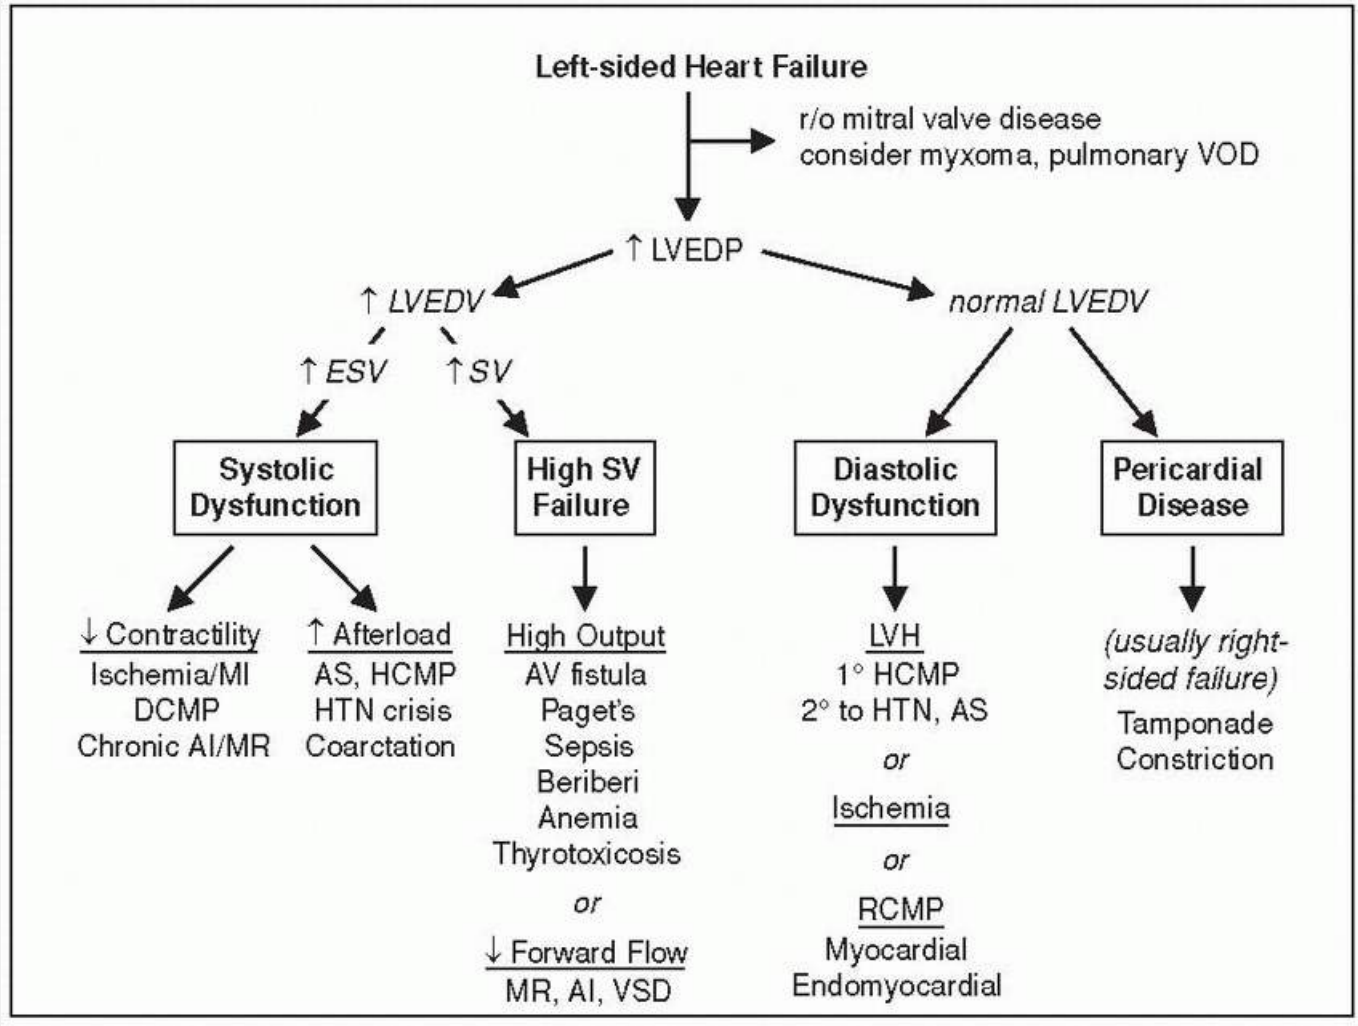

Figure 1-3 Approach to left-sided heart failure

History

- Low output: fatigue, weakness, exercise intolerance, Δ MS, anorexia
- Congestive: dyspnea, weight gain;

left-sided → orthopnea, paroxysmal nocturnal dyspnea

right-sided → peripheral edema, RUQ discomfort, bloating, early satiety

Stages in the Development of Heart Failure (*Circ* 2009;119:e391)

- A: At high **risk for HF**, but w/o structural heart disease or symptoms of HF
- B: **Structural heart disease**, but w/o signs or symptoms of HF
- C: Structural heart disease w/ prior or current **symptoms of HF**
- D: **Refractory heart failure** requiring specialized intervention

Functional classification (New York Heart Association class)

- Class I: no sx w/ ordinary activity; class II: sx w/ ordinary activity;

  class III: sx w/ minimal activity; class IV: sx at rest

Physical exam ("2-minute" hemodynamic profile; *JAMA* 1996;275:630 & 2002;287:628)

- **Congestion ("dry" vs "wet")**

  ↑ JVP (˜80% of the time RAP > 10 mmHg → PCWP >22 mmHg; *JHLT* 1999;18:1126)

  ⊕ hepatojugular reflux: ≥4 cm ↑ in JVP that persists for ≥15 sec w/ abdominal pressure Se/Sp 73/87% for RA >8 and Se/Sp 55/83% for PCWP >15 (*AJC* 1990;66:1002)

  Abnl Valsalva response: square wave (↑ SBP w/ strain), no overshoot (no ↑ BP after strain) S_3 (in Pts w/ HF → ˜40% ↑ risk of HF hosp. or pump failure death; *NEJM* 2001;345:574) rales, dullness at base 2° pleural effus. (*often absent* in chronic HF due to lymphatic compensation) ± hepatomegaly, ascites and jaundice, peripheral edema
- **Perfusion ("warm" *vs* "cold"): narrow pulse pressure (<25% of SBP) → CI <2.2 (91% Se, 83% Sp; *JAMA* 1989;261:884)**; other signs of low perfusion include soft S_1 (↑ dP/dt), pulsus alternans, cool & pale extremities, ↓ UOP, muscle atrophy
- Other signs to look for: periodic breathing/Cheyne-Stokes resp., abnl PMI (diffuse, sustained or lifting depending on cause of HF), S_4 (diast. dysfxn), murmur (valvular disease, ↑ MV or TV annulus, displaced papillary muscles), ↓ carotid upstroke

Evaluation for the presence of heart failure

- CXR (see Radiology insert): pulm edema, pleural effusions ± cardiomegaly, cephalization, Kerley B-lines
- BNP/NT-proBNP can help exclude HF; levels ↑ w/ age, renal dysfxn, AF, ↓ w/ obesity Se ≥95%, Sp ˜50%, PPV ˜65%, NPV ≥94% for HF in Pts p/w SOB (*BMJ* 2015;350:h910)
- Evidence of ↓ organ perfusion: ↑ Cr, ↓ Na, abnl LFTs
- Echo (see inserts): ↓ EF & ↑ chamber size ↑ systolic dysfxn; hypertrophy, abnl MV inflow, abnl tissue Doppler → ? diastolic dysfxn; abnl valves or pericardium; ↑ estimated RVSP
- PA catheterization: ↑ PCWP, ↓ CO and ↑ SVR (in low-output failure)

Evaluation of the potential causes of heart failure

- **ECG:** Q waves or PRWP (ischemic heart disease); LVH (hypertensive heart disease or HCM); low limb lead voltage (NICM or infiltrative); heart block (infiltrative)
- **TTE:** LV & RV size & function, valvular disease (and whether likely 1° or 2° to CMP), findings indicative of infiltrative or pericardial disease
- **Coronary angio** (or noninvasive imaging, eg, CT angio); if no CAD, w/u for NICM
- **Cardiac MRI:** multiparameter evaluation of cardiac structure & function including:

  LVEF, RVEF and volumes; regional wall motion abnormalities

  presence, pattern, & extent of myocardial scar (using late gadolinium enhancement, LGE) w/ Se/Sp of 100%/96% vs coronary angio for dx etiology of HF (*Circ* 2011;124:1351)

  myocardial inflammation or infiltration (eg, myocarditis, sarcoidosis, amyloidosis) restriction vs constrictive pericardial disease

Evaluation of Potential Causes of Heart Failure

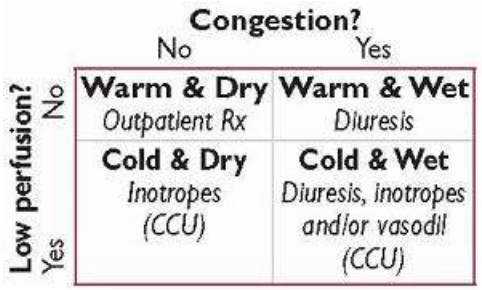
Etiology	ECG Pattern	Imaging Pattern
Ischemia, infarct	ST segment deviation, Qw	TTE: regional WMA, ± thinning/aneurysm Cor angio/CTA: obstructive CAD MRI: subendocardial or transmural LGE
Infiltrative	Low limb lead voltage, ± heart block, pseudoinfarct	TTE: LVH, "starry sky," ↑ biatrial size → amyloid MRI: inapprop nulling of myocardium + diffuse LGE → amyloid; patchy LV + RV LGE → sarcoidosis; ↓ T2 star → iron overload
Idiopathic DCM	Low limb lead volts, precordial LVH, BBB	TTE: 4 chamber dilation, diffuse hypokinesis MRI: mid-myocardial LGE
Tachy-myopathy	Persistent SVT	TTE: diffuse hypokinesis MRI: absent LGE in early stage
Myo(peri) -carditis	Pseudoischemia/-infarct. Pericard: diffuse concave STE w/ ST:T ratio >0.24 in V_6 and PR depression	TTE: typically global HK MRI: mid-myocardial + epicardial LGE, ↑ T2 and ↑ T1 ratios (edema)

Precipitants of acute heart failure

- **Dietary indiscretion or medical nonadherence** (˜40% of cases)
- **Myocardial ischemia or infarction** (˜10-15% of cases); myocarditis
- **Renal failure** (acute, progression of CKD, or insufficient dialysis) → ↑ preload

- **Hypertensive crisis (incl. from RAS), worsening AS** → ↑ left-sided afterload
- **Drugs** (βB, CCB, NSAIDs, TZDs), **chemo** (anthracyclines, trastuzumab), or **toxins** (EtOH)
- **Arrhythmias;** acute valv. dysfxn (eg, endocarditis), espec mitral or aortic regurgitation
- **COPD or PE** → ↑ right-sided afterload; **RV pacing**
- Other: **extreme emotional stress; anemia,** systemic **infection, thyroid** disease

Treatment of acute decompensated heart failure



- Assess degree of congestion & adequacy of perfusion
- For **congestion: "LMNOP"**

  Lasix IV w/ monitoring of UOP; total daily dose 2.5× usual daily PO dose → ↑ UOP, but transient ↑ in renal dysfxn vs 1× usual dose; Ø clear diff between cont gtt vs q12h dosing (*NEJM* 2011;364:797)

  Morphine (↓ sx, venodilator, ↓ afterload)

  Nitrates (venodilator)

  Oxygen ± noninvasive vent (↓ sx, ↑ P_aO_2; no Δ mortality; see "Mechanical Ventilation")

  Position (sitting up & legs dangling over side of bed → ↓ preload)

- For **low perfusion**, see below

- Adjustment of oral meds

  ACEI/ARB: hold if HoTN, consider Δ to hydralazine & nitrates if renal decompensation βB: reduce dose by at least ½ if mod HF, d/c if severe HF and/or need inotropes

Overview of Treatment of Heart Failure by Stage

Pt characteristics		Therapy
A	HTN, DM, CAD Cardiotoxin exposure FHx of CMP	Treat HTN, lipids, DM, SVT Stop smoking, EtOH; ↑ exercise ACEI/ARB if HTN/DM/CAD/PAD
B	Prior MI, ↓ EF, LVH or asx valvular dis.	All measures for stage A + ACEI/ARB & βB if MI/CAD or ↓ EF. ? ICD.
C	Overt HF	All measures for stage A, ACEI, βB, diuretics, Na restrict ↓ EF: aldo antag, ICD, consider CRT, nitrate/hydral, dig.

D	Sx despite max med Rx 4-y mortality >50%	All measures for stages A-C Consider IV inotropes, VAD, transplant, end-of-life care

- Utility of BNP-guided Rx remains debated (*Circ* 2013;301:500 & 509)
- Implantable PA pressure sensor in NYHA III → 37% ↓ risk of hosp (23% for HFrEF; 52% for HFpEF) (*Lancet* 2011;377:658)

Treatment of advanced heart failure (*Circ* 2009;119:e391)

- Consider PAC (qv) if not resp to Rx, unsure re: vol status, HoTN, ↑ Cr, need inotropes
- Tailored Rx w/ PAC; goals of MAP >60, CI >2.2 (MVO_2 >60%), SVR <800, PCWP <18
- **IV vasodilators:** NTG, nitroprusside (risk of coronary steal if CAD; prolonged use → cyanide/thiocyanate toxicity); nesiritide (rBNP) not rec for routine use (*NEJM* 2011;365:32)
- **Inotropes:** in addition to ↑ inotropy, consider additional properties:

  dobutamine: vasodilation at doses ≤5 mcg/kg/min; mild ↑ PVR; desensitization over time

  dopamine: splanchnic vasodil. → ↑ GFR & natriuresis; vasoconstrictor at ≥5 mcg/kg/min; does not enhance decongestion or preserve renal fxn in ADHF (*JAMA* 2013;310:2533)

  milrinone: prominent systemic & pulmonary vasodilation; ↑ dose by 50% in renal failure
- Ultrafiltration: similar wt loss to aggressive diuresis, but ↑ renal failure (*NEJM* 2012:367:2296)
- **Mechanical circulatory support (MCS)** (*JHLT* 2013;32:157; *JACC* 2015;65:e7 & 2542)

  Temporary MCS*:* depending on the device (Table), can be placed percutaneously or surgically to support LV or RV, as a bridge to recovery, for periprocedural support, or as a bridge to decision regarding transplant or durable long-term MCS

  Intra-aortic balloon pump (IABP): inflates in diastole & deflates in systole to ↓ impedance to LV ejection of blood, ↓ myocardial O_2 demand & ↑ coronary perfusion

  Axial flow pumps (eg, Impella): Archimedes screw principle in LV

  Extracorporeal magnetically levitated centrifugal pumps (eg, TandemHeart & CentraMag)

  Extracorporeal membrane oxygenation (ECMO, *Circ* 2015;131:676)

Short-Term Mechanical Circulatory Support in Cardiogenic Shock

Device	IABP	Impella 2.5 & CP	Impella 5.0	Tandem	CentriMag	ECMO
Max support (L/min)	0.5	2.5 & 3-4	5.0	5.0	10	6
RV support	N	Y (2^{nd} dev.)	N	Y (2^{nd} dev.)	Y (2^{nd} dev.)	Y

Support duration	wks	~4 wk	~4 wk	<4 wk	mos	wks
Percutan?	Y	Y	N	Y	N	Y
Contraindic.	≥ mod AI, severe PAD	LV thrombus, mech AV, severe AS		coagulop severe PAD	coagulop	coagulop

(*Circ* 2011;123:533 & 126:1717; *JACC* 2015;65:e7)

Durable Long-term MCS*:* surgically placed LVAD ± RVAD as bridge to recovery (*NEJM* 2006;355:1873) or transplant (HeartMate II or HeartWare LVAD or Total Artificial Heart if biventricular failure), or as destination Rx (HeartMate I: 52% ↓ 1-y mort. vs med Rx; *NEJM* 2001;345:1435, HeartMate II: 24% ↑ mort. vs HeartMate 1; *NEJM* 2009;361:2241)

- **Cardiac transplantation:** curative Rx but supply of organs limited (~2500/y in U.S.) 10% mortality in 1st year, median survival ~10 y

  Contraindications: active malignancy or infection, irreversible PHT (TPG>15, PVR>5WU despite pulmonary vasodilator Rx), active substance abuse or lack of social supports

  Relative contraindications: age (eg, >70 y), other end organ dysfunction (liver, kidney, lung, unless dual organ transplantation is performed)

Treatment of Chronic Heart Failure with Reduced Ejection Fraction

Diet, exercise	Na <2 g/d, fluid restriction, exercise training in ambulatory Pts
ACEI	↓ mortality: 40% in NYHA IV, 16% in NYHA II/III, 20-30% in asx but ↓ EF (*NEJM* 1992;327:685 & *Lancet* 2000;355:1575) High-dose more effic. than low. Watch for ↑ Cr, ↑ K (ameliorate by low-K diet, diuretics, Kayexalate; patiromer, another K binder, under review; *NEJM* 2015;372:211), cough, angioedema.
ATII receptor blockers (ARBs)	*Consider as alternative if cannot tolerate ACEI (eg, b/c cough)* Noninferior to ACEI (*Lancet* 2000;355:1582 & 2003;362:772) As with ACEI, higher doses more efficacious (*Lancet* 2009;374:1840) Adding to ACEI → ↑ risk of ↑ K and ↑ Cr (*BMJ* 2013;346:f360)
ARNi (ARB + neprilysin inhib)	Neutral endopeptidase (NEP, aka neprilysin) degrades natriuretic peptides as well as bradykinin & angiotensins. LCZ696 = valsartan + sacubitril (NEPi): ↓ CV mort & HF hosp c/w ACEi; more HoTN and trend to more angioedema (PARADIGM-HF, *NEJM* 2014;371:993).
Hydralazine + nitrates	*Consider if cannot tolerate ACEI/ARB or in blacks w/ NYHA III/IV* 25% ↓ mort. (*NEJM* 1986;314:1547); infer. to ACEI (*NEJM* 1991;325:303) 43% ↓ mort. in blacks on standard Rx (A-HEFT, *NEJM* 2004;351:2049)

β-blocker (data for carvedilol, metoprolol, bisoprolol)	*EF will transiently* ↓, *then* ↑. *Contraindic. in decompensated HF.* 35% ↓ mort. & 40% ↓ rehosp. in NYHA II-IV (*JAMA* 2002;287:883) Carvedilol superior to low-dose metop in 1 trial (*Lancet* 2003;362:7), but meta-analysis suggests no diff between βB (*BMJ* 2013;346:f55).
Aldosterone antagonists	*Consider if adeq. renal fxn and w/o hyperkalemia; watch for* → *K* 24-30% ↓ mort. in NYHA II-IV & EF ≤35% (*NEJM* 2011;364:11) 15% ↓ mort. in HF post-MI, EF ≤40% (EPHESUS, *NEJM* 2003;348:1309)
Cardiac resynch therapy (CRT, qv)	*Consider if EF* ≤35%, *LBBB and symptomatic HF* 36% ↓ mort. & ↑ EF in NYHA III-IV (CARE-HF, *NEJM* 2005;352:1539) 41% ↓ mort. if EF ≤30%, LBBB and NYHA I/II (*NEJM* 2014;370:1694)
ICD (see "Cardiac Rhythm Mgmt Devices")	*Use for* 1° *prevention if EF* ≤30-*35% or 2° prevention; not if NYHA IV* ↓ mort. in ischemic & non-isch CMP; no Δ mort. early post-MI (*NEJM* 2004;351:2481 & 2009;361:1427), ∴ wait ≥40 d
Diuretics	Loop ± thiazide diuretics (sx relief; no mortality benefit)
Digoxin	23% ↓ HF hosp., no Δ mort (*NEJM* 1997;336:525); ? ↑ mort w/ ↑ levels (*NEJM* 2002;347:1403); optimal 0.5-0.8 ng/mL (*JAMA* 2003;289:871)
Ivabradine (*If* blocker w/o ⊖ ino)	*Consider if HR* >70, *NSR on max βB.* 18% ↓ CV mort or HF hosp (*Lancet* 2010;376:875)
ω-3 fatty acids	9% ↓ mortality (included HF with normal LVEF) (*Lancet* 2008:372:1223)
IV iron supplementation	*? if NYHA II/III, EF* ≤40%, *Fe-defic* (ferritin <100 or ferritin 100-300 & TSAT <20%). ↓ Sx, ↑ 6MWD, independent of Hct (*NEJM* 2009;361:2436).
Anticoagulation	*If AF, VTE, LV thrombus,* ± *if large akinetic LV segments* In SR w/ EF <35%, ↓ isch stroke, but ↑ bleed (*NEJM* 2012;366:1859)
Heart rhythm	Catheter ablation of AF → ↑ in EF, ↓ sx (*NEJM* 2004;351:2373) No mortality benefit to AF rhythm vs rate cntl (*NEJM* 2008;358:2667) Pulm vein isolation ↓ sx c/w AVN ablation & CRT (*NEJM* 2008;359:1778)
Meds to avoid	NSAIDs, nondihydropyridine CCB, TZDs
Experimental	Serelaxin ± ↓ dyspnea & ? ↓ mortality (*Lancet* 2013;381:29)

(*Circ* 2009;119:e391; *NEJM* 2010;362:228; *Lancet* 2011;378:713 & 722)

Heart failure with preserved EF (HFpEF; "Diastolic HF") (*Circ* 2011;124:e540)

- Epidemiology: ~½ of Pts w/ HF have normal or only min. impaired systolic fxn (EF ≥40%); risk factors for HFpEF incl ↑ age, ♀, DM, AF. Mortality ≈ to those w/ systolic dysfxn.
- Etiologies (impaired relaxation and/or ↑ passive stiffness): ischemia, prior MI, LVH, HCMP infiltrative CMP, RCMP aging, hypothyroidism
- Precipitants of pulmonary edema: *volume overload* (poor compliance of LV → sensitive to even modest ↑ in volume); *ischemia* (↓ relaxation); *tachycardia* (↓ filling time in diastole), AF (loss of atrial boost to LV filling); HTN (↓ afterload → ↓ stroke volume)
- Dx w/ clinical s/s of HF w/ preserved systolic fxn. Dx supported by evidence of diast dysfxn:

  (1) echo: abnl MV inflow (E/A reversal and Δs in E wave deceleration time) & ↓ myocardial relax. (↑ isovol relax. time & ↓ early diastole tissue Doppler velocities)

  (2) exercise-induced ↑ PCWP (± ↓ response chronotropic & vasodilator reserve)
- Treatment: diuresis for vol overload, BP control, prevention of tachycardia and ischemia; no benefit to: ACEI/ARB (*NEJM* 2008;359:2456) or PDE5 inhib (*JAMA* 2013;309:1268) spironolactone ↓ CV death & HF hosp (at least in Americas) (*NEJM* 2014;370:1383);

  ARNi (*Lancet* 2012;380:1387) and serelaxin (*Lancet* 2013;381:29) under study

PA CATHETER AND TAILORED THERAPY

Rationale

- Cardiac output (CO) = SV × HR; LV SV depends on LV end-diastolic volume (LVEDV) ∴ manipulate LVEDV to optimize CO while minimizing pulmonary edema
- Balloon at tip of catheter inflated → floats into "wedge" position. Column of blood extends from tip of catheter, through pulmonary circulation, to a point just proximal to LA. Under conditions of no flow, PCWP ≈ LA pressure ≈ LVEDP, which is proportional to LVEDV.
- Situations in which these basic assumptions fail:

  (1) Catheter tip not in West lung zone 3 (and ∴ PCWP = alveolar pressure ≠ LA pressure); clues include lack of *a* & *v* waves and if PA diastolic pressure < PCWP

  (2) PCWP > LA pressure (eg, mediastinal fibrosis, pulmonary VOD, PV stenosis)

  (3) Mean LA pressure > LVEDP (eg, MR, MS)

  (4) Δ LVEDP-LVEDV relationship (ie, abnl compliance, ["nl" LVEDP may not be optimal)

Indications (*Circ* 2009;119:e391; *NEJM* 2013;369:e35)

- **Diagnosis and evaluation**

  Ddx of shock (cardiogenic vs distributive; espec if trial of IVF failed or is high risk) and of pulmonary edema (cardiogenic vs not; espec if trial of diuretic failed or is high risk)

  Evaluation of CO, intracardiac shunt, pulmonary HTN, MR, tamponade, cardiorenal syndrome

  Evaluation of unexplained dyspnea (PAC during provocation w/ exercise, vasodilator)
- **Therapeutics** (*Circ* 2006;113:1020)

Tailored therapy to optimize PCWP, SV, $S_{MV}O_2$, RAP, & PVR, in heart failure or shock

Guide to vasodilator therapy (eg, inhaled NO) in pulm HTN, RV infarction

Guide to perioperative management in some high-risk Pts, pretransplantation

Guide to candidacy for thoracic organ transplantation and mechanical circulatory support

- **Contraindications**

  Absolute: right-sided endocarditis, thrombus/mass or mechanical valve; PE

  Relative: coagulopathy (reverse), recent PPM or ICD (place under fluoroscopy), LBBB (˜5% risk of RBBB ↑ CHB, place under fluoro), bioprosthetic R-sided valve

Efficacy concerns (*NEJM* 2006;354:2213; *JAMA* 2005;294:1664)

- No benefit to routine PAC use in high-risk surgery, sepsis, ARDS
- No benefit in decompensated HF (*JAMA* 2005;294:1625); untested in cardiogenic shock
- But: ˜½ of CO & PCWP clinical estimates incorrect; CVP & PCWP not well correl.; ∴ use PAC to (a) answer hemodynamic ? and then remove, or (b) manage cardiogenic shock

Pulmonary Artery Catheter Features

Component	cm from distal tip	Function
Distal lumen	0	Sampling of blood for $S_{MV}O_2$
1.5-mL balloon	0.5	Inflation allows flow directed placement & determination of PCWP
Thermistor	4	Detection of temp Δ for CO calc
Proximal injectate port	26	Infusions & injection of saline for CO calc
Additional Optional Features		
Fiberoptic O_2 sat sensor	0	Allows continuous measurement of $S_{MV}O_2$
Thermal filament	˜10-25	Allows continuous CO calc by thermodilution
Pacing port	˜19	Allows placement of pacing wire in RV
Infusion port(s)	˜30	Additional infusion port(s)

Placement

- Insertion site: **R internal jugular** or **L subclavian veins** for "anatomic" flotation into PA
- **Inflate** balloon (max 1.5 mL) when **advancing** and to **measure PCWP**
- Use resistance to inflation and pressure tracing to avoid overinflation & risk of PA rupture
- Should require 1-1.5 mL air in balloon to float into wedge (<1 mL → pull PAC back; no PCWP at 1.5 mL → advance)
- **Deflate** balloon when **withdrawing** and at all other times
- CXR should be obtained after placement to assess for catheter position and PTX
- If catheter cannot be successfully floated (typically if severe TR or RV dilatation) or if another relative contraindication exists, use fluoroscopic guidance

Complications

- **Central venous access:** pneumo/hemothorax (~1%), arterial puncture (if inadvertent cannulation w/ dilation → surgical/endovasc eval), air embolism, thoracic duct injury
- **Arrhythmias:** ½ PVCs, 20% NSVT, 3% VT (minimize time PAC tip in RV); RBBB (5%)

- **Inability to advance:** difficulty RA → RV seen w/ lg RA and/or severe TR; difficulty RV → PA seen w/ lg RV; deflate balloon, withdraw 10 cm, inflate balloon & readvance. *If repeated attempts unsuccessful at bedside, then perform under fluoro* (to avoid PAC coiling & potentially knotting, which would require interventional cardiology to extract).
- **PA rupture:** risk factors include prolonged balloon inflation, PHT, anticoag. Presents w/ hemoptysis and, if severe, hypoxemia & hypovolemic shock. *Keep balloon inflated, intubate w/ dbl-lumen endotracheal tube, lateral decubitus position with affected side down, STAT interventional radiology and/or thoracic surgery consultation.*
- **Air embolism:** presents w/ dyspnea, chest pain, ↑ R-sided pressures, HoTN. *Place in Trendelenburg, high-flow* O_2.
- **Other:** infxn (espec if PAC >3 d old); thrombus; pulm infarction; valve/chordae damage

Intracardiac pressures

- Zero the transducer and level it with the right atrium (phlebostatic axis)
- Transmural pressure (≈ preload) = measured intracardiac pressure - intrathoracic pressure
- Intrathoracic pressure (usually slightly ⊖) is transmitted to vessels and heart
- **Always measure intracardiac pressure at end-expiration**, when intrathoracic pressure closest to 0 ("high point" in spont. breathing Pts; "low point" in Pts on ⊕ pressure vent.)
- If ↑ intrathoracic pressure (eg, PEEP), measured PCWP *overestimates* true transmural pressures. Can approx by subtracting ~½ PEEP (× ¾ to convert cm H2O to mmHg).
- PCWP: LV preload best estimated at *a* wave; risk of pulmonary edema from avg PCWP

Cardiac output

- **Thermodilution:** saline injected in RA. Δ in temp over time measured at thermistor (in PA) is integrated and is ≈ 1/CO. Inaccurate if ↓ CO, severe TR or shunt.
- **Fick method:** O_2 consumpt ([V with dot above]O_2) (L/min) = CO (L/min) × Δ arteriovenous O_2 content

  ∴ CO = [V with dot above]O_2 /C(a-v)O_2

  [V with dot above]O_2 ideally measured (espec if ↑ metab demands), but freq estimated (125 mL/min/m^2)

  C(a-v)O_2 = [10 × 1.36 mL O_2/g of Hb × Hb g/dL × (S_aO_2-$S_{MV}O_2$)]

  $S_{MV}O_2$ is key variable that Δs *with acute interventions*

  If $S_{MV}O_2$ >80%, consider if the PAC is "wedged" (ie, pulm vein sat), L→ R shunt, impaired O_2 utilization (severe sepsis, cyanide, carbon monoxide), ↑ ↑ FiO_2

PA Catheter Waveforms

Location	RA	RV	PA	PCWP
Distance	~20 cm	~30 cm	~40 cm	~50 cm
Normal Pressure (mmHg)	mean ≤6	syst 15-30 diast 1-8	syst 15-30 mean 9-18 diast 6-12	mean ≤12
Waves				
Comment	*a* = atrial contraction, occurs in PR interval *c* = bulging of TV back into RA at start of systole *x* = atrial relaxation and descent of base of heart *v* = blood entering RA, occurs mid-T wave *y* = blood exiting RA after TV opens at start of diastole	RVEDP occurs right before upstroke and ≥ mean RA pressure unless there is TS or TR	Waveform should contain notch (closure of pulmonic valve). Peak *during* T wave PA systolic = RV systolic unless there is a gradient (eg, PS). PA diastolic ≈ PCWP unless ↑ trans-pulm gradient (eg, ↑ PVR).	Similar to RA except *dampened* and *delayed. a* wave *after* QRS, ± distinct *c* wave, *v* wave *after* T (helps distinguish PCWP w/ large *v* waves 2° MR from PA).

PCWP waveform abnormalities: large *a* wave → ? mitral stenosis; large *v* wave → ? mitral regurgitation; blunted *y* descent → ? tamponade; steep *x* & *y* descents → ? constriction.

Hemodynamic Profiles of Various Forms of Shock

Type of shock	RA	PCWP	CO	SVR
Hypovolemic	↓	↓	↓	↓
Distributive	variable	variable	usually ↑ (but can be ↓ in sepsis)	↓
Cardiogenic: 1° L-sided (eg, acute MI)	nl or ↑	↑	↓	↑
Cardiogenic: 1° R-sided (eg, RV infarct; PE)	↑	nl or ↓	↓	↑
Tamponade	↑	↑	↓	↑

Surrogates: JVP ≈ RA; pulmonary edema on CXR implies ↑ PCWP; UOP ∝ CO (barring AKI); delayed capillary refill (ie, >2-3 sec) implies ↑ SVR

Tailored therapy and management of shock (*Circ* 2009;119:e391)

- **Goals:** optimize both MAP and CO to promote end-organ perfusion, while ↓ risk of pulmonary edema & systemic venous congestion MAP = CO × SVR; CO = HR × SV (depends on preload, afterload and contractility) pulmonary edema when PCWP >20-25 (↑ levels may be tolerated in chronic HF) hepatic and renal congestion when CVP/RAP >15 mmHg
- **Optimize preload** = LVEDV ≈ LVEDP ≈ LAP ≈ PCWP (*NEJM* 1973;289:1263) goal **PCWP ˜14-18 in acute MI,** ≤1 **4 in acute decompensated HF** optimize in individual Pt by measuring SV w/ different PCWP to create Starling curve ↑ by giving NS (albumin w/o clinical benefit over NS; PRBC if significant anemia) ↓ by diuresis (qv), ultrafiltration or dialysis if refractory to diuretics
- **Optimize afterload** ≈ wall stress during LV ejection = [(˜SBP × radius) / (2 × wall thick.)] and ∴ ∝ MAP and ∝ SVR = (MAP - CVP / CO); goals: **MAP >60, SVR 800-1200** MAP >60 & SVR ↑ : vasodilators (eg, nitroprusside, NTG, ACEI, hydral.) or wean pressors MAP <60 & SVR ↑ (& ∴ CO ↓): temporize w/ pressors until can ↑ CO (see below) MAP <60 & SVR low/nl (& ∴ inappropriate vasoplegia): vasopressors (eg, norepinephrine [α, β], dopamine [D, α, β], phenylephrine [α] or vasopressin [V_1] if refractory)
- **Optimize contractility** ∝ CO for given preload & afterload; **goal CI = (CO / BSA) >2.2** if too low despite optimal preload & vasodilators (as MAP permits):

  ⊕ *inotropes:* eg, dobutamine (mod inotrope & mild vasodilator) or milrinone (strong inotrope & vasodilator, incl

pulm), both proarrhythmic, or epi (strong inotrope & pressor)

mechanical support devices: eg, IABP, percutaneous or surgical VAD (L-sided, R-sided, or both) or ECMO (*Circ* 2011;123:533)

Vasopressors and Inotropes Used in Shock

Drug	Receptors			Hemodynamics				Comment
	α_1	β_1	β_2	SVR	MAP	HR	CO	
Phenylephrine	+++	0	0	↑↑↑	↑↑	↓↓[a]	↓[a]	↑ PVR
Vasopressin[b]	0	0	0	↑↑↑	↑↑	↓↓[a]	↓[a]	↔PVR; ∴ attractive if RV dysfxn or PHT
Norepinephrine	+++	++	+	↑↑↑	↑↑	↔/↑	↔/↑	Better outcomes than w/ dopa
Epinephrine	+++	+++	+++	↓ / ↑[c]	↑	↑↑	↑	β predom at low doses
Isoproterenol	0	+++	+++	↓↓	↓	↑↑ ↑	↑↑	⊕ chronotrope
Dobutamine	+	+++	++	↓	↔/↓	↑↑	↑↑	↓ PCWP
Dopamine[d]	+	++	0	↔/↑[d]	↔/↑[d]	↑↑ ↑	↑	
Milrinone[e]	0	0	0	↓↓	↓	↔	↑↑ ↑	↓↓ PCWP; ↓ PVR; ∴ attractive if RV dysfxn or PHT

[a]Bradycardia seen due to vagal reflex if hypertension; ↓ CO due to ↑ afterload

[b]V_1 agonist

[c]Low doses ↓ SVR, high doses ↑ SVR

[d]Also a (D) dopa receptor agonist; 0.5-2 mcg/kg/min → D; 2-10 → D & β_1; > 10 → α_1, β_1, D

[e]PDE_3 inhibitor

CARDIOMYOPATHIES

Diseases with mechanical and/or electrical dysfunction of the myocardium

DILATED CARDIOMYOPATHY (DCM)

Definition and epidemiology (*Circ* 2013;128:e240; *JACC* 2013;62:2046)

- Ventricular dilatation and ↓ contractility ± ↓ wall thickness *in the absence of myocardial disease caused by ischemia/infarct, valvular disease or hypertension*
- Ventricular dysfunction usually global but can be regional variation
- May be accompanied by significant MR & TR due to impaired leaflet coaptation
- Incidence: 5-8/100,000/y; prevalence: 1/2500. Most common reason for heart transplant.

Etiologies (*JACC* 2011;57:1641; *Circ Res* 2012;111:131)

- **Familial** (>35%): defined as having DCM and at least 2 closely related family members with otherwise unexplained DCM; usually autosomal dominant pattern of inheritance; ~30 genes identified to date, encoding structural & nuclear proteins *sarcomere:* eg, titin (*TTN,* ~20%; *NEJM* 2012;366:619); β- & α-myosin heavy chain (*MYH7, MYH6,* ~5% each); troponin T (*TNNT2,* ~5%)

  nuclear envelope: eg, lamin A/C (*LMNA,* ~5%), often w/ conduction system disease (eg, sinus brady, AV block, atrial arrhythmias) (*NEJM* 2009;341:1715)

  ion channel: eg, Na channel (*SCN5A,* <5%), same gene as for LQTS & Brugada *Z-disc:* eg, myopalladin (*MYPN,* <5%), ankyrin (*ANKRD1,* <5%) *cytoskeletal:* eg, desmin (DES, <1%); dystrophin (*DMD,* <1%) *syndromic disorders:* eg, muscular dystrophies (Duchenne/Becker; limb-girdle)
- **Idiopathic** (<20%): ? undiagnosed infectious, alcoholic or genetic cause (in ~1/4 of Pts w/ "idiopathic" DCM, evidence of DCM found in 1° relative, suggesting undx genetic)
- **Infectious myocarditis** (10-15%, autoimmune response; *Lancet* 2012;379:738)

  Viruses (parvoB19 & HHV6 > coxsackie, adeno, echo, CMV, HCV): from subacute (dilated LV; mild-mod dysfxn) to fulminant (nondil., thick, edematous LV; sev dysfxn)

  Bacterial, fungal, rickettsial, TB, Lyme (mild myocarditis, often with AVB, qv)

  HIV: ~8% of asx HIV ⊕; due to HIV, 2° infxns, or antiretrovirals; HIV also associated w/ premature CAD (*JACC* 2012;59:779)

  Chagas: apical aneurysm ± thrombus, RBBB, megaesophagus/colon (*NEJM* 2015;373:456)
- **Toxic**

  alcohol (20-35%; *Prog* CV *Dis* 2010;52:289): typically 7-8 drinks/d × >5 y, but variable; male > female, typical age 30-55, may resolve w/ abstinence

  cocaine (primarily myocardial ischemia, but DCM is also seen); amphetamines & ephedra; anabolic steroids

  XRT (usually RCM); cobalt; chloroquine anthracyclines: risk ↑ >550 mg/m^2, may manifest late; usually irreversible cyclophosphamide, taxoids, mitomycin-C, 5-fluorouracil, and interferons trastuzumab: usually reversible
- **Infiltrative** (5%): often mix of DCM + RCM (qv) with thickened walls sarcoidosis, amyloidosis, hemochromatosis, tumor

- **Autoimmune**

  collagen vasc. dis./vasculitis (˜5%): PM, SLE, scleroderma, PAN, RA, Wegener's;

  peripartum (last month → 5 mo postpartum; *EHJ* 2015;36:1090): ˜1:3000 preg. ↑ risk w/ multiparity, ↑ age, Afr Am; stnd HF Rx except if preg then select drugs based on safety; ? bromocriptine to ↓ prolactin; 72% normalize EF; predictors of poor recovery include EF <30% & LVEDD ≥6 cm (*JACC* 2015;66:905); even if nl EF, ˜30% recur w/ next preg

  idiopathic giant cell myocarditis (GCM): avg age 42 y, may present as severe HF, high-grade AV block, or VT, historically poor prognosis (<6 mo median transplant-free survival; *NEJM* 1997;336:1860), but with modern immunosuppression 67% achieve HF remission with transplant-free survival of 77% at 1 y (*Circ* HF 2013;6:15)

  eosinophilic (variable peripheral eos): hypersensitivity (mild HF but at risk for SCD) or acute necrotizing eosinophilic myocarditis (ANEM; STE, effusion, severe HF)

- **Stress-induced** (Takotsubo = apical ballooning)

  typically seen in postmenopausal ♀ after psychological stressor

  ? due to catecholamine surge → microvasc dysfxn & Ca overload mimics MI (pain, ± STE & ↑ Tn; deep TWI & ↑ QT); mid/apex dyskinesis, sometimes w/ cardiogenic shock (caution w/ pressors as can induce LV outflow tract obstruction)

  ? Rx w/ βB, ACEI, anticoag if LV thrombus (but usually not just for dyskinesis given rapid resolution); usually improves over wks (*JAMA* 2011;306:277)

- **Tachycardia:** likelihood ∝ duration & rate (although avg HR ˜120); often resolves w/ rate control, which is only way to definitely make dx, over several mos (*Circ* 2005;112:1092)

- **Arrhythmogenic (right ventricular) cardiomyopathy** (ACM, formerly ARVC): see below

- **Metabolic/other**

  hypothyroidism, acromegaly, pheo; OSA; cirrhosis thiamine, selenium or carnitine deficiency

- **LV noncompaction:** see below

Clinical manifestations

- **Heart failure:** both congestive & poor forward flow sx; signs of L- & R-sided HF **diffuse**, **laterally displaced PMI**, **S3**, ± MR or TR (annular dilat., displaced pap. muscle)
- Embolic events (˜10%), supraventricular/ventricular arrhythmias, & palpitations
- Chest pain can be seen w/ some etiologies (eg, myocarditis)

Diagnostic studies and workup

- CXR: moderate to marked cardiomegaly, ± pulmonary edema & pleural effusions
- ECG: may see PRWP, Q waves or BBB; low-voltage; AF (20%); may be normal
- Echocardiogram: LV dilatation, ↓ EF, *regional or global* LV HK ± RV HK, ± mural thrombi
